This dissertation is part of the examination and has not been corrected after defense for eventual errors. Use as a reference is permitted subject to written approval of the promotor stated on the front page.

Acknowledgment

First of all, I would like to deeply thank my supervisors Koenraad and Sam. Koenraad, I am very grateful for your endless availability and always being ready to listen, give advice and guide me through the whole research process and yet let it be my own work entirely. Sam, thank you for sharing your passionate drone knowledge and pilot experience with me. Flying with such expensive equipment with no prior experience was scary at first but with your guidance it became a wonderful experience.

I would also like to thank Marjel Van den Boer for the high-quality photo reportage during our flight mission in Hechtel-Eksel. Your photos make my thesis and presentation much more illustrative. Additionally, thank you Stephanie Delalieux for your guidance using the MAPEO Field Software to pre-process our data.

Last but not least, I would like to express my sincere gratitude to my boyfriend, family and friends for always supporting and encouraging me during this master thesis as well as during my entire study. A special thanks to my dad for investing a lot of time in reading and giving suggestions during the writing process.

Thank you all for helping to turn this thesis into something I can be proud of!

Scientific Summary

Today, biodiversity is declining faster than ever known in human history. This huge loss of species causes a decrease in ecosystem functioning which is a direct threat to human existence. To be able to take conservation and restoration actions, inventory and monitoring biodiversity and the associated ecosystem functioning is crucial. Unmanned aircraft systems (UAS) are in this regard a cost-efficient method to collect high spatial resolution data compared to for example field surveys. However, the relation between UAS-based data and biodiversity is still underexamined.

In this master thesis, we tried to predict species diversity and productivity at the FORBIO tree experiment sites in Belgium, by collecting and linking multispectral drone imagery with ground truth data on species richness and composition. The mean, standard deviation and correlation of variance of the six different reflectance bands (red, green, blue, red edge, near-infrared and thermal), the normalised difference vegetation index and the subtracted plant height were used for modelling. The model coefficient of determination (R^2) values to predict species richness with spectral data, spectral heterogeneity data, plant height data and all data combined were respectively 0.16, 0.13, 0.26 and 0.33. These results showed that UAS-based tree height data are a better predictor of species richness compared to spectral data.

The models to predict plant height, used as a proxy for tree productivity, had R^2 -values of 0.72 and 0.69 based on spectral data and species richness data, respectively. In 80% of the mixed plots, a positive net diversity effect was observed. The latter in combination with the model results confirms the biodiversity-productivity hypothesis. These thesis results indicate that UAS-based data can indeed be used in tree biodiversity and productivity studies in addition to field surveys.

1 Literature Study

1.1 Biodiversity in Natural Ecosystems

1.1.1 Importance

Biodiversity, including all biotic variation at gene, species, and ecosystem level, is essential, not only for human existence but for all life on Earth (Cardinale et al., 2012). Its importance as being part of the biophysical ecosystem structure has gotten more recognition during the past decades (Haines-Young & Potschin, 2010). Ecosystems provide all kinds of socio-economic and ecological benefits to humans, called ecosystem services (ES). There are four categories distinguished by the Millennium Ecosystem Assessment: provisioning, regulating, cultural, and supporting ecosystem services, with the first three directly affecting human well-being and the latter maintaining the other three (Millennium Ecosystem Assessment, 2005). The biological underpinning that determines the supply of these ES are ecosystem functions (EF) (Oliver et al., 2015).

Understanding how biodiversity affects ecosystem functioning, and therefore human well-being, has grown significantly over the past decades (Cardinale et al., 2012). In many studies, biodiversity is considered to be a positive determinant of ecosystem functions and dynamics (Schwartz et al., 2000; Tilman et al., 2014). Increased species richness can result for example in higher productivity, better nutrient dynamics, or increased ecosystem stability (Singh, 2002; Tilman, 2001).

The term 'overyielding' is often used to refer to the higher productivity in a species-rich ecosystem. There are two main mechanisms that can explain this biodiversity-productivity hypothesis relation. On the one hand, there is the selection effect. In a polyculture, the chance of well-performing species being present is higher as well as the chance that they will become dominant and thus increase productivity (Jing et al., 2021). On the other hand, productivity can increase in polycultures due to complementarity between different species. This can have different causes. For example, resources can be used more efficiently when species differentiate from one another in niche e.g. differentiation in rooting depth and/or architecture (Van de Peer et al., 2018). Facilitation and mutualism between different species is another example that positively influences the species productivity (Jing et al., 2021). Contrary to

selection, complementarity can also explain cases of transgressive overyielding, i.e. mixtures that have a higher productivity than the most productive monoculture (Tilman et al., 2014). When considering wood production in forest systems, complementarity is a more important mechanism than selection (Jing et al., 2021).

An important part of biodiversity is functional diversity. It is the variety of functional traits (e.g. rooting depth, leaf phenology, flowering time) that influence aspects of ecosystem functioning like ecosystem dynamics, stability and productivity (Tilman, 2001). High functional diversity in a species pool can have an even higher importance for ecosystem functioning, due to complementarity between different species, mainly when considering multiple EF (Haines-Young & Potschin, 2010).

The impact of biodiversity on EF is nonlinear and saturates at high diversity (Figure 1-1). This means that, in general, loss of biodiversity in a species-rich ecosystem will not have the same impact as in a species-poor ecosystem. The lower the biodiversity already is, the higher the decrease in EF and ES delivery when losing extra species (Cardinale et al., 2012). Also, the capacity of an ecosystem to buffer environmental perturbations will decrease rapidly. The so-called ‘insurance effect’ of biodiversity will no longer ensure the stability of ecosystem functioning at a low number of species (Oliver et al., 2015).

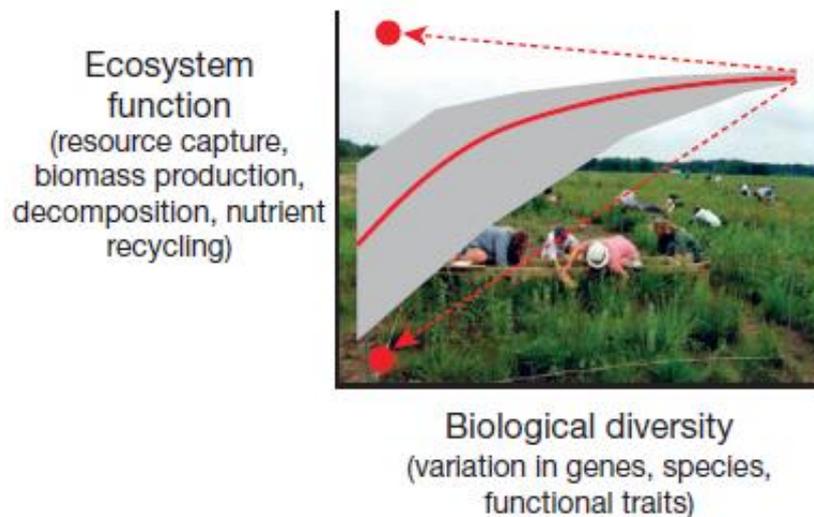

Figure 1-1 The nonlinear relationship between ecosystem functioning and biological biodiversity, based on several hundred experiments. The red line indicates the average change and the grey polygon the 95% confidence interval. The upper and bottom red dots show respectively the maximum and minimum value of the most and the least productive species grown in a monoculture (copied from Cardinale et al., 2012).

1.1.2 Biodiversity Crisis

In the past, in total five major mass extinctions have occurred and scientists suggest that today we are living in an ongoing sixth mass extinction with human activity as its main driver (Ceballos et al., 2010; Rampino & Shen, 2021; Roberts et al., 2021). Contrary to what many people think, extinction is an essential phenomenon for evolution since the balance between speciation and extinction determines diversification (Rull, 2022). The natural background extinction rate depends on natural selection processes such as competition, climatic changes and predation. When the extinction rate exceeds this background rate in orders of magnitude, one speaks of an episodic extinction (Rull, 2022). However, an episodic extinction burst is only considered as a mass extinction when also more than 75% of the living species are lost in a geologically short period of time (Barnosky et al., 2011).

Based on fossil records, the mean natural background extinction rate for all taxa is estimated at 0.1 extinctions per million species-year (E/MSY). In other words, globally one extinction per 100,000 species occurs on average every 100 years. Today, this rate is between 1,000 and 10,000 times higher (Ceballos et al., 2010; Singh, 2002; Figure 1-2). Unlike the rate, the magnitude of extinction has not yet reached the 75% boundary to speak of mass extinction. According to the Red List of Threatened Species drawn up by the International Union for Conservation of Nature and Natural Resources (IUCN), around 900 of the evaluated species went extinct in the past 500 years. This is only 0.04% of the 2.0 million known species and 0.01% of the 8.7 million estimated species (Bánki et al., 2022; Mora et al., 2011). However, these percentages are underestimations since only 142,577 species have already been assessed by the IUCN. The evaluated species are unevenly divided across different species groups, which makes it impossible to draw conclusions or make extrapolations for the insufficiently covered groups (IUCN, 2022).

The IUCN divides the assessed species into nine different categories depending on their risk of global extinction. Compared to the number of extinct species, the number of threatened species, which include all vulnerable, endangered and critically endangered species, are already much higher and increasing faster than ever seen in human history (Figure 1-3). Twenty-eight percent of all evaluated species are threatened and according to the seventh global assessment report on biodiversity and

ecosystem services, around 1/9th of all plant and animal species on Earth are threatened (IPBES, 2019; IUCN, 2022).

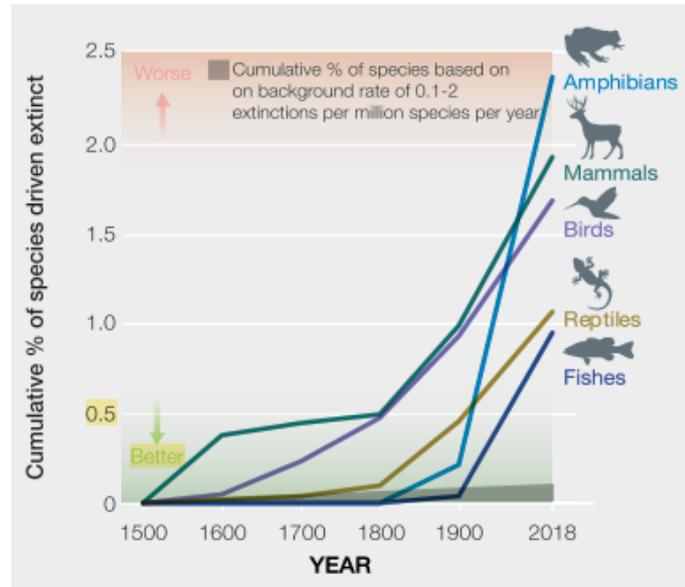

Figure 1-2 Cumulative extinction rate ('extinct' or 'extinct in the wild') of vertebrate species since 1500. The grey shape represents the extinction percentages expected with a background extinction rate of 0.1-2 E/MYS. In total 77% of described vertebrate species have been evaluated (copied from IPBES, 2019).

When extrapolating the current extinction rate and taking into account the large number of threatened species, the benchmark of 75% will be reached in a geologically short time interval of less than 1.8 million years (Rull, 2022). So, when no actions are undertaken to conserve biodiversity, we can state that today we are facing the start of a sixth mass extinction even though the extinction magnitude is not very large yet.

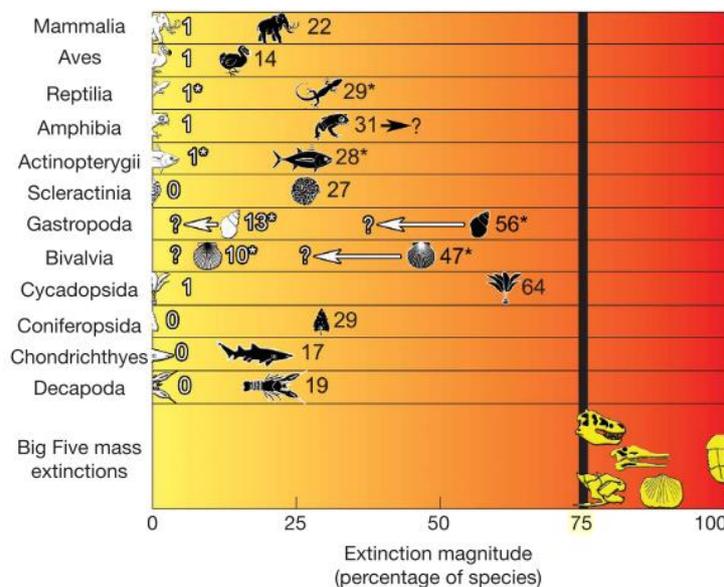

Figure 1-3 Magnitudes of IUCN-assessed extinct (white) and threatened species (black) for different taxa over the past 500 years (copied from Barnosky et al., 2011).

Both direct and indirect anthropogenic drivers are causing this huge global loss in biodiversity. Examples of direct drivers are changes in land and sea use, direct exploitation of organisms, climate change, pollution, and invasion of alien species. Indirect drivers are the underlying causes of these direct drivers, for example, human population dynamics, conflicts, epidemics, trade, etc. Without taking action to reduce the impact of these direct and indirect drivers, the global rate of species extinction will accelerate even more (IPBES, 2019).

Although there is a clear global decreasing trend in biodiversity, different patterns are observed locally and regionally (Vellend et al., 2017; Figure 1-4). Immigration and invasion become important additional inputs next to speciation when evaluating regional or local species pools (Singh, 2002). At the regional scale, biodiversity has increased over time due to the higher levels of established introduced species compared to the number of regionally extinct species (Sax & Gaines, 2003). Most of the introductions of non-native species are human-mediated, either accidentally or intentionally (Vellend et al., 2017). The species composition becomes more similar in different regions because these non-native species spread around the world. Part of these introduced species are invasive, for example because their natural enemies are not present. Therefore, native specialist species experience higher extinction rates (Millennium Ecosystem Assessment, 2005). This global biotic homogenisation is the reason why the increased regional biodiversity does not induce global biodiversity gain (Cardinale et al., 2012).

Locally, the temporal biodiversity trends strongly differ depending on the context. For example, overexploitation in an intensive agricultural system or excessive nitrogen deposition generally cause a local loss of biodiversity. Other drivers such as climate change, habitat fragmentation, and pollution can decrease, increase or have no effect on the number, composition, and distribution of species (Vellend et al., 2017). Local extinctions are also dependent on the coextinction of different species (Koh et al., 2004). When a certain species disappears, it can influence other species that locally depend on each other. Local biodiversity loss can have a direct impact on the local provision of certain ES, like flood and drought control, pollination, pest control etc. and therefore on the well-being of local communities (Díaz-Delgado et al., 2019; Haines-Young & Potschin, 2010).

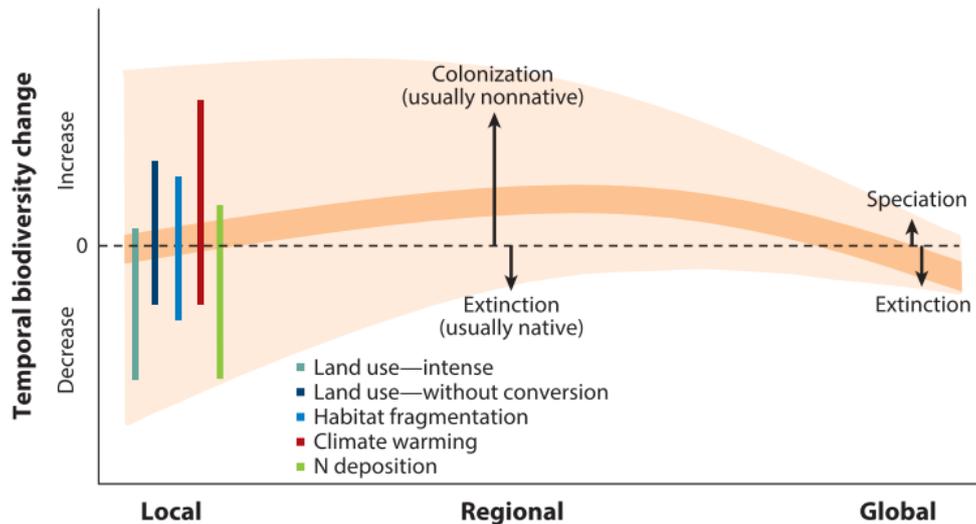

Figure 1-4 Temporal plant biodiversity change at different spatial scales. The large, shaded polygon represents the range of possible outcomes, with the central tendency indicated by the thick, darker curve. The coloured bars represent the range of local-scale outcomes of different drivers of change (copied from Vellend et al., 2017).

Not only species but also genetic diversity is declining due to human activity. According to the Food and Agriculture Organisation (FAO), already 75% of all genetic crop diversity is lost during the past century (FAO, 1999). Local varieties are lost because of the global use of genetically adapted and uniform, high-yielding crops. This loss poses a serious threat to global food security since the resilience against pests, diseases and climate change declines drastically (IPBES, 2019). The ability to breed crops in the future with desired traits such as drought tolerance decreases as well since the gene pool becomes smaller when numerous crop varieties disappear. The loss of genetic diversity today, which reduces the potential for subsequent evolutionary change, is even more alarming than the loss of species diversity (Singh, 2002).

1.1.3 Ecosystem Monitoring

Because of this ongoing loss of global biodiversity, the functioning and thereby the services delivered by natural ecosystems are highly threatened (Oliver et al., 2015). Therefore, conservation and restoration of biodiversity should be one of the major global priorities (Tilman et al., 2014). To do so, quick, efficient, and accurate inventory and monitoring of biodiversity and the associated ecosystem functioning in natural ecosystems is crucial.

First, it is important to point out that different measures can be used to evaluate and monitor biodiversity. Species diversity, being the most used measure of biodiversity, is often used as a synonym for species richness (Cardinale et al., 2012). However, it

actually should refer to both the number of species and the equitability between them (Whittaker et al., 2001). In other words, species diversity covers species richness on the one hand and species evenness on the other hand.

Functional diversity is an interesting facet of biodiversity to measure as well because of its strong relation with ecosystem functioning as discussed in section 1.1.1. Different measuring tools are used depending on the functional traits of interest, which as mentioned before influence the species' performance. Often knowing which species are present in a species pool is enough to evaluate the functional diversity because when species are described, most of their functional traits are listed as well. Lastly, genetic diversity is also often used as a measure of biodiversity because of its importance to maintain the stability of ecosystems. Molecular techniques are needed to sample the genetic variation among individuals of the same species (Singh, 2002).

To monitor species productivity, the above- and belowground biomass should be measured. This can be done directly by taking field samples and analyse the biomass in a laboratory. However, often less destructive methods are applied, mainly in forest systems, to measure the productivity. Diameter growth and tree height measures are used to monitor the standing biomass. Since the leaf area index (LAI)¹ is positively related to tree productivity, it is also often used as a measure (Arias et al., 2007).

To conduct a biodiversity assessment and inventory at a local or regional scale, often point sampling methods based on field visits are used (Singh, 2002). For productivity inventory, biomass estimates are often made in the field as well. Albeit being very accurate, field sampling has multiple limitations in this regard because these measurements are very costly and time-consuming. It is also not always easy to extrapolate these point measurements to a larger scale. Therefore, remote sensing can be an important alternative. Although it is often less accurate because it does not directly measure the variables of interest (see further), it is faster, non-destructive, relatively cheap and often easier to repeat and extrapolate (Jones & Vaughan, 2010).

¹ Leaf Area Index (LAI) is a unitless index defined as the one-side projected leaf area per unit ground surface (Arias et al., 2007).

1.2 Remote Sensing with Drones

1.2.1 General Sensor and Platform Characteristics

Remote sensing (RS) is defined as collecting information about a target from a distance without touching it (Khorram et al., 2012). More specifically, when talking about RS for earth observation, one often refers to the detection of electromagnetic radiation (EMR) by artificial detectors to study natural and non-natural ecosystems and their functioning (Jones & Vaughan, 2010). A wide variety of imaging sensors with different characteristics and applications is available. Each sensor has a specific spectral, spatial and temporal resolution and is active or passive sensing (Toth & Józków, 2016).

The spectral region of a sensor is determining for which applications the collected data can be used. The electromagnetic spectrum can be divided into three major groups that are used for RS: the optical part of the spectrum, which consists of visible and near-infrared radiation (NIR), the infrared part, and the microwave part of the spectrum (Figure 1-5). The infrared region is further subdivided in two subregions: the shortwave infrared (SWIR) and the longwave infrared (LWIR), also referred to as the thermal infrared (TIR). The longer the wavelength, the less energy the wave contains and thus the harder it becomes to get information about radiation further in the spectrum (Khorram et al., 2012).

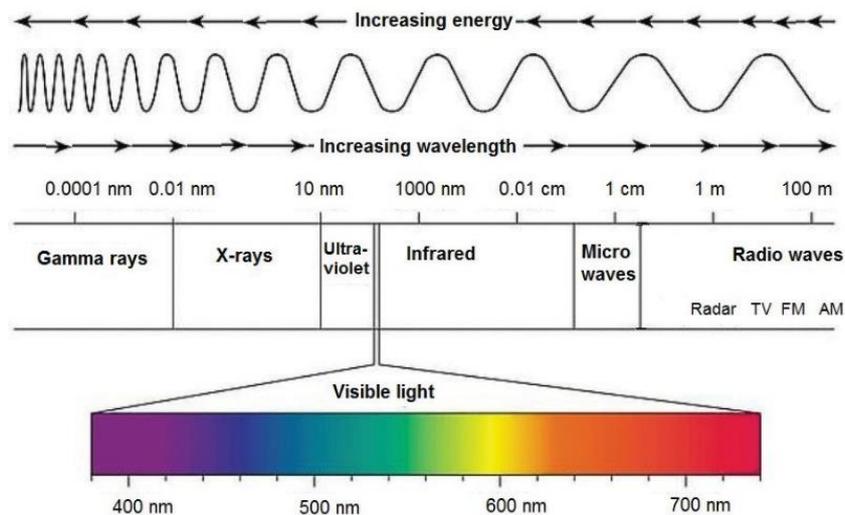

Figure 1-5 Electromagnetic spectrum with the optical (visible: 400-700 nm & near infrared part: 700-1000 nm), the infrared (shortwave infrared: 1-4 μm & thermal infrared: 4-6 μm & 8-14 μm) and the microwave (0.01-1 m) part of the spectrum often used for remote sensing applications (copied from Zhu et al., 2018).

The number and width of the measured electromagnetic bands determine the *spectral resolution* of a sensor. When hundreds of often single-nm spectral bands are measured, one speaks about hyperspectral imagery (Govender et al., 2007).

Multispectral imagery has a lower spectral resolution and thus fewer but wider bands are captured by the sensor (Toth & Jóźków, 2016). More information is averaged together and therefore less detailed information can be obtained per pixel with a multispectral sensor. However, for a lot of applications multispectral imagery is already detailed enough, definitely when the data can be collected at a high spatial resolution such as with UAVs (Dash et al., 2018).

The *spatial resolution* is often expressed in ground sampling distance (GSD) and can vary between a kilometre and centimetre resolution depending on the sensor, the platform and its intended flight altitude (Toth & Jóźków, 2016). The *temporal resolution* or repeat time is defined as how fast the same area can be revisited and resampled by the sensor. Lastly, the difference between *active and passive sensors* depends on the type of energy source used (Shaw & Burke, 2003). A passive sensor uses solar radiation as light source and captures the reflectance or emittance of objects, vegetation, or the atmosphere. Active sensors make use of their own energy source: the sensor sends out a signal and measures the difference in time, polarization and/or intensity of the returned signal (Zhu et al., 2018). Therefore, active sensors may be less dependent on environmental circumstances such as illumination conditions (Toth & Jóźków, 2016). An example of an active sensor is a light detection and ranging (LiDAR) sensor, where a laser pulse is used to measure the distance to the surface, from which a digital elevation model can be constructed.

This wide variety of sensors can be attached to different types of platforms: spaceborne platforms (satellites) or airborne platforms (e.g. aircraft, drones, hot air balloons). Satellites often have a high temporal resolution, but a relatively low spatial resolution. Aircraft, on the contrary, have a high spatial resolution but the flights are very costly and therefore difficult to repeat. Unmanned aircraft systems (UAS) – also called drones, unmanned aerial vehicles or remotely piloted aircraft systems – can collect spatially very detailed data and these flights are easy and relatively cheap to repeat. Therefore, UAS, such as drones, are very useful for numerous applications, for example, to assess the biodiversity of ecosystems.

1.2.2 Drones: The Way to Go?

UAS technology has developed rapidly over the last decade with new imaging sensors and better data processing methods (Toth & Jóźków, 2016). This increasing interest in

drone applications is reflected by the increasing trend of drone-related research (Chabot, 2018; Tsiamis et al., 2019). The use of drones shows some clear advantages compared to other RS techniques and field surveys. First of all, the use of UAS is highly flexible and easy to repeat, because the flying path is not fixed as with satellites and UAS are easy to transport (Dash et al., 2018; Pajares, 2015). UAS can operate both rapidly and at a relatively low cost (Candiago et al., 2015). In contrast, aircraft operations are in a lot of cases expensive because an entire flying crew needs to be stand-by, often for several days, to be able to take off when the weather conditions are favourable (Jones & Vaughan, 2010). A European license to fly with a UAS in open class A1 and A3 – as specified by the European Union Aviation Safety Agency (EASA) – can be obtained by everyone after taking a free online theoretical exam and is valid in all countries in Europe. A licence in these subclasses of the open category is in most cases sufficient to conduct biodiversity assessment flights since you generally do not need to fly over or near uninvolved people (EASA, 2021). The data captured by UAS generally has an extremely high spatial (centimetres) resolution because of their low overflight height (Pajares, 2015). Furthermore, drones can give access to inhospitable places where field operations would be too dangerous or destructive, e.g. mountainous areas, large wildfires, flooded areas etc. (Jones & Vaughan, 2010). Satellites can also measure such data, but the overpass time of satellites is fixed, and natural disasters are not, neither in place nor in time.

However, like every technique, UAS also has some disadvantages. Compared to satellites and aircrafts the spatial coverage of a drone flight is small due to the low flying altitude and the limited battery power. Because of that spatially specific context, it will not always be possible to extrapolate developed analysing techniques or conclusions to other areas of interest. UAS are, like aircraft, less stable platforms than satellites. They are more sensitive to wind and other disturbances, which can result in a less accurate positioning (Jones & Vaughan, 2010). UAS do not have a fixed overpass time like satellites, which could be a drawback for long-term monitoring applications. However, some studies show that combining spatially-detailed UAS data with satellite imagery can deliver results with higher utility than both separate datasets (Dash et al., 2018). Depending on the type of sensor attached to the UAS, the flight possibilities will be limited to certain weather conditions. A drone flies below the clouds, but a passive sensor onboard still uses the sun as an energy source and therefore it is

better to execute a flight during constant light intensity to have a representative reflectance for the whole research area. Nevertheless, depending on the intended application useful imagery can be captured even in presence of full cloud cover (Dash et al., 2018). Drones can have an extra sensor on top to capture the incoming solar radiation so that the reflected radiation can be corrected for it. Another limiting factor in the use of UAS is the different flight area restrictions present in almost every country. Although the UAS open class A1 and A3 licence allows pilots to fly in all European countries, they still need to follow the specific flight area restrictions in their region of interest. In certain areas, interference with other aerial vehicles and both security and privacy issues make that strict rules need to be followed when using UAS.

1.2.3 Biodiversity Assessment with Drones

Spectral Signature of Vegetation

When sensors measure radiation in multiple bands over a sufficiently wide range of the electromagnetic spectrum, the result, a spectral signature, can be used to identify materials and/or characteristics of the measured object or surface (Shaw & Burke, 2003). Vegetation can be distinguished from water, soil, or man-made materials through its specific spectral signature, but also different vegetation types or species can be differentiated (Figure 1-6). However, the latter can only be done with a high spatial and spectral resolution being available. In that case, different parts of the spectral signature of vegetation can even provide information about health, possible water stress, leaf maturity, etc. (Jones & Vaughan, 2010).

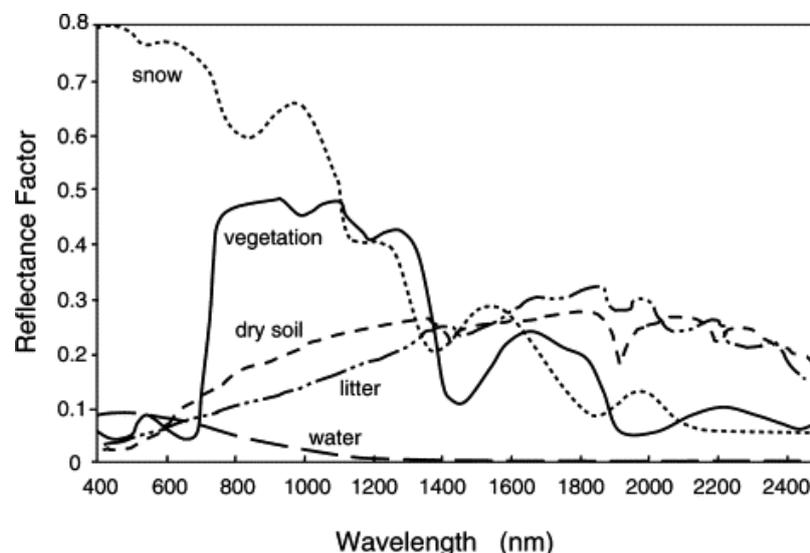

Figure 1-6 Spectral reflectance signatures of different land cover types: healthy vegetation, dry soil, grass litter, water, and snow (copied from Huete, 2004).

To be able to extract plant biophysical parameters and physiological characteristics of vegetation from reflectance data, the interaction between vegetation and incoming radiation needs to be well understood (Pajares, 2015). The typical spectral reflectance of a single healthy leaf is low in both the visible and SWIR part of the spectrum and high in the NIR part of the spectrum (Figure 1-7).

In the visible part of the spectrum, around 80 to 90% of the photosynthetic active radiation is absorbed by different leaf pigments (Jones & Vaughan, 2010). Chlorophyll is the dominant photosynthetic pigment in green plants and strongly absorbs red and blue wavelengths. Therefore, a small reflectance peak can be seen around the green waveband for healthy vegetation, which we perceive as green because of the same reason (Govender et al., 2007). The chlorophyll concentration decreases when leaves are exposed to environmental stress or are senescing during autumn. In that case, carotene and xanthophyll, absorbing blue wavelengths, and anthocyanin, absorbing blue and green wavelengths, become more dominant, hence the reflection in the red waveband increases (Jones & Vaughan, 2010). To conclude, reflectance data of the visible part of the spectrum allows to distinguish vegetation depending on their colour and maturity.

The dominant factor controlling the leaf reflectance in the NIR part of the spectrum is the cell structure. Typically, between 40 and 50% of the incoming radiation is reflected, but it can vary depending on the cellular arrangements within the leaf that determine internal scattering (Govender et al., 2007). Dicots generally have a dorsiventral leaf structure with a lot of air and asymmetric structures which causes scattering inside the leaf while monocots have a more compact leaf structure that allows less scattering and thus more absorption and less reflectance (Jones & Vaughan, 2010). Also, sun leaves and older leaves generally have a less compact structure and can therefore be distinguished from shadow leaves and younger leaves based on NIR reflectance data. The sharp increase between the red waveband and the NIR plateau is called the red edge and can be used as a proxy for plant stress (Huete, 2004).

Three water absorption bands can be found in the SWIR around 1450 nm, 1950 nm and 2500 nm (Jones & Vaughan, 2010). When a leaf is under water stress less radiation will be absorbed in these bands and thus more light is reflected. The lignin and cellulose content are two other main factors influencing the reflectance in the SWIR region. In the TIR part of the spectrum, vegetation reflectance is too low to

measure with remote sensing applications (Zhu et al., 2018). However, the emissivity in these wavelengths is high when vegetation wants to get rid of excess energy. It is related to the leaf temperature and transpiration and can therefore be linked to changes in plant metabolism (Jones & Vaughan, 2010).

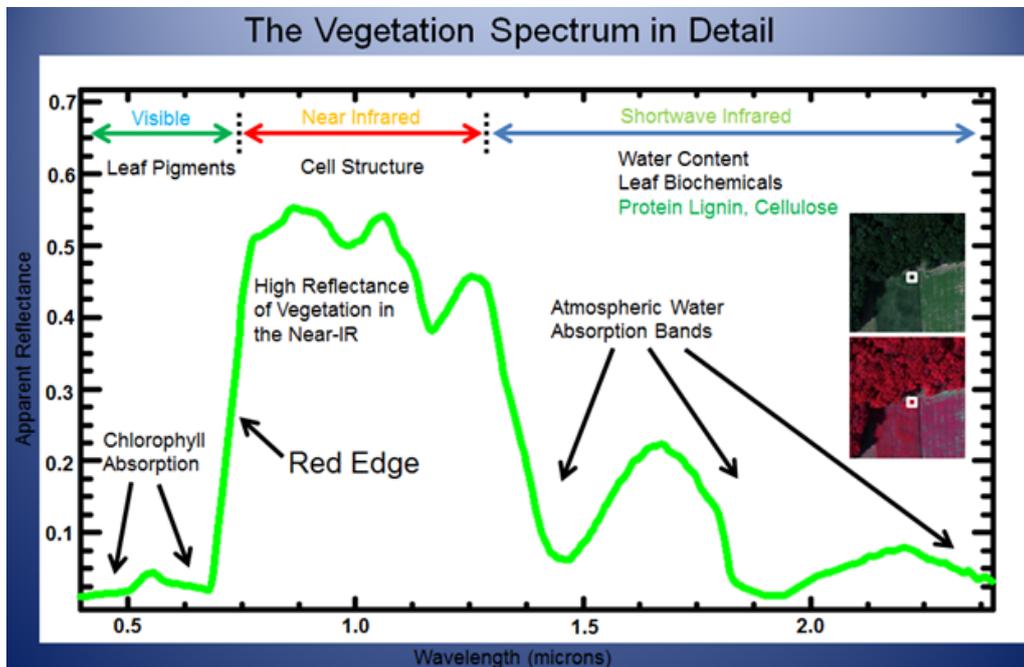

Figure 1-7 Typical spectral reflectance signature of healthy green vegetation (copied from Kirkaya, 2020).

This typical spectral reflectance signature is solely determined by the radiative characteristics of individual leaf components. It is the result of single-leaf measurements with a spectroradiometer that uses a perpendicular incoming light beam. However, the reflectance data collected with a UAS is the result of the interaction between incoming radiation and the entire vegetation canopy rather than single leaves (Pajares, 2015). Overall, the reflectance is lower than of a single leaf measurement because of variations in leaf orientation, illumination angle, and shadow. A part of the reflected signal is also attenuated due to interaction with the soil or other non-foliage background surfaces (Jones & Vaughan, 2010). The latter is less pronounced when using UAS compared to for example satellites because there are no mixed pixels in cm-resolution images. On the other hand, volume scattering, being the scattering caused by transmission and reflection across the multiple leaf layers in the canopy, can compensate for that reduction in reflectance. In canopies with a high LAI, more volume scattering will take place resulting in higher reflectance, mainly in NIR, compared to canopies with a low LAI.

Translation to Biodiversity Measures

With passive sensors on board a UAS, a stack of images is created for every pixel with every image representing another waveband (Shaw & Burke, 2003). That results in a 3D data cube, with two spatial dimensions (x and y) and one spectral dimension (z), which contains the different spectral channels. There are different approaches to translate this spectral data cube in information for assessing biodiversity.

A simple, widely-used method to distinguish vegetation is calculating spectral indices from certain bands of the spectral signature. One of the most known ratios is the normalized difference vegetation index (NDVI). A band in the near-infrared part of the spectrum is compared with a band in the red part of the spectrum by taking the normalized difference as the name suggests (Zhu et al., 2018):

$$NDVI = \frac{NIR-RED}{NIR+RED} \quad (1.1)$$

As discussed in the previous section, plants subjected to stress show a higher reflectance in the red waveband and a lower reflectance in the NIR part of the spectrum, resulting in a smaller normalised difference. Studies show that this ratio is indeed correlated with the amount of physiological stress, but also with the amount of vegetation cover, the plant condition, and the photosynthetic activity (Dash et al., 2018). Therefore, variation in NDVI can be used as a proxy for species richness (Peng et al., 2019). Other commonly-used indices to distinguish different vegetation types that simultaneously correct for soil background are the soil-adjusted vegetation index, and the modified soil-adjusted vegetation index (Govender et al., 2007).

The spectral variation hypothesis (SVH) suggests that high biodiversity may show high spectral heterogeneity and low biodiversity low spectral heterogeneity (Rocchini et al., 2007). Therefore, the calculation of spectral heterogeneity captured by UAS throughout a study area may be used as a proxy for the functional diversity or species diversity (Peng et al., 2019). The standard deviation (sd) or another measure to capture the variance can be calculated for single, multiple or combination of bands and then be linked with the species richness. The variance metrics show a positive correlation with the species diversity according to the SVH. However, an important condition is that the grain size of the studied ecosystem matches the spatial resolution of the RS-data. When collecting for example high spatial resolution data of plant individuals that

are larger than the pixel size, an object-based classification needs to be done before applying the SVH. Otherwise, the spectral variation inside one object will also be considered as species diversity. Furthermore, all the pixels that add additional unwanted variation, such as roads, need to be masked out. In some studies or study areas, no evidence is found confirming the SVH, often because of not applying one of these conditions (Gholizadeh et al., 2020; Möckel et al., 2016; Peng et al., 2019). Hyperspectral data seems to be better for linking spectral heterogeneity with species richness compared to multispectral data because the right selection of bands is very crucial (Rocchini et al., 2007).

Most forest biodiversity studies using UAS-collected multispectral data, indirectly estimate biodiversity through species classification rather than directly determining a measure of biodiversity (Franklin & Ahmed, 2018; Peng et al., 2021; Xu et al., 2020). This method requires knowledge about the spectral signature of the different species present in the study area but has an overall high accuracy. Segmentation of deciduous tree species is found more difficult than conifer tree species, generally resulting in a lower classification accuracy (Franklin & Ahmed, 2018). Several studies indicate that adding a structural component significantly improves the accuracy of classification (Gini et al., 2018; Peng et al., 2021). UAS-derived photogrammetric products can be used in that regard as alternative for expensive LiDAR surveys (González-Jaramillo et al., 2019).

The direct method of using spectral heterogeneity as proxy of species diversity, is mostly tested with satellite imagery for forest ecosystems (Gholizadeh et al., 2020). Generally, low but significant determination coefficients are found using simple univariate models to link spectral heterogeneity with local species richness (Peng et al., 2019; Rocchini et al., 2018). Some studies document that the success of the SVH might be season dependent and strongly is affected by the choice of spectral heterogeneity measures (Madonsela et al., 2021). Overall, no consistent success of using specific vegetation or spectral heterogeneity indices to predict species richness is achieved. Only a limited amount of studies have assessed the possibility of UAS, or remote sensing in general, to monitor forest biodiversity over time (Gholizadeh et al., 2020). Another bottleneck nowadays in forest remote sensing is model transferability. Most of the UAS-based models are region and vegetation specific whereby it is not yet

possible to apply them to other study areas or make useful comparisons (Peng et al., 2019; Toivonen et al., 2021).

To conclude, the development of methods for estimating functional and species diversity based on fine-scaled UAS data has still a big growth potential. A lot of different spectral indices have been developed and evaluated to predict plant alpha-diversity. However, because of the large variability in RS platforms, sensors and vegetation types, consensus about an optimal spectral index that directly relates species diversity with spectral data is yet to be found.

1.3 Research Goals

Biodiversity loss is one of the most pressing global problems nowadays. Hand in hand with species, a lot of ecosystem functions and services are diminishing. To be able to take conservation and restoration actions, capturing accurate data frequently throughout time is needed. UAS imagery with high spectral, spatial, and temporal resolution could be crucial means to do so.

Given the potential of using multispectral drone data, drone flight missions were conducted at the different sites of the FORBIO tree experiment to assess the effectiveness in predicting tree species diversity and productivity. We extracted both spectral and plant height data from the UAS imagery and used it to build models to predict tree species richness on the one hand and tree species productivity on the other hand by combining the multispectral data with ground truth data. We also documented a pipeline of the steps of collecting, processing and analysing drone data that can be used as manual for future research using drones. In this thesis, the following more specific research questions will be answered:

- Is it possible to predict species identity, composition and/or richness based on multispectral drone data?
- Which bands or band combinations are most suitable to do so?
- Will adding a structural vegetation component, i.e. plant height, increase the accuracy?
- Can the productivity be modelled based on multispectral drone data?
- Is the biodiversity-productivity hypothesis valid?
- How can the process of collecting drone data be optimized?

2 Materials and Methods

2.1 Study Sites

The study was performed in the three sites of the FORBIO (FORest BIODiversity and Ecosystem Functioning) experiment distributed across Belgium: Hechtel-Eksel, Zedelgem and Gedinne (Figure 2-1). Between 2009 and 2012 the FORBIO experiment was established to assess the effect of tree species diversity on forest biodiversity and ecosystem functioning. This long-term tree experiment is part of the largest worldwide network of biodiversity experiments TreeDivNet (Verheyen et al., 2013). Each FORBIO site is subdivided into different plots where trees are planted in monocultures or mixtures with two to four species (Figure 2-1). Because the abiotic conditions are constant at a site while the species diversity differs between the plots, forest biodiversity dynamics can easily be evaluated. Although the experimental design is similar for each site, the soil and climatological characteristics differ.

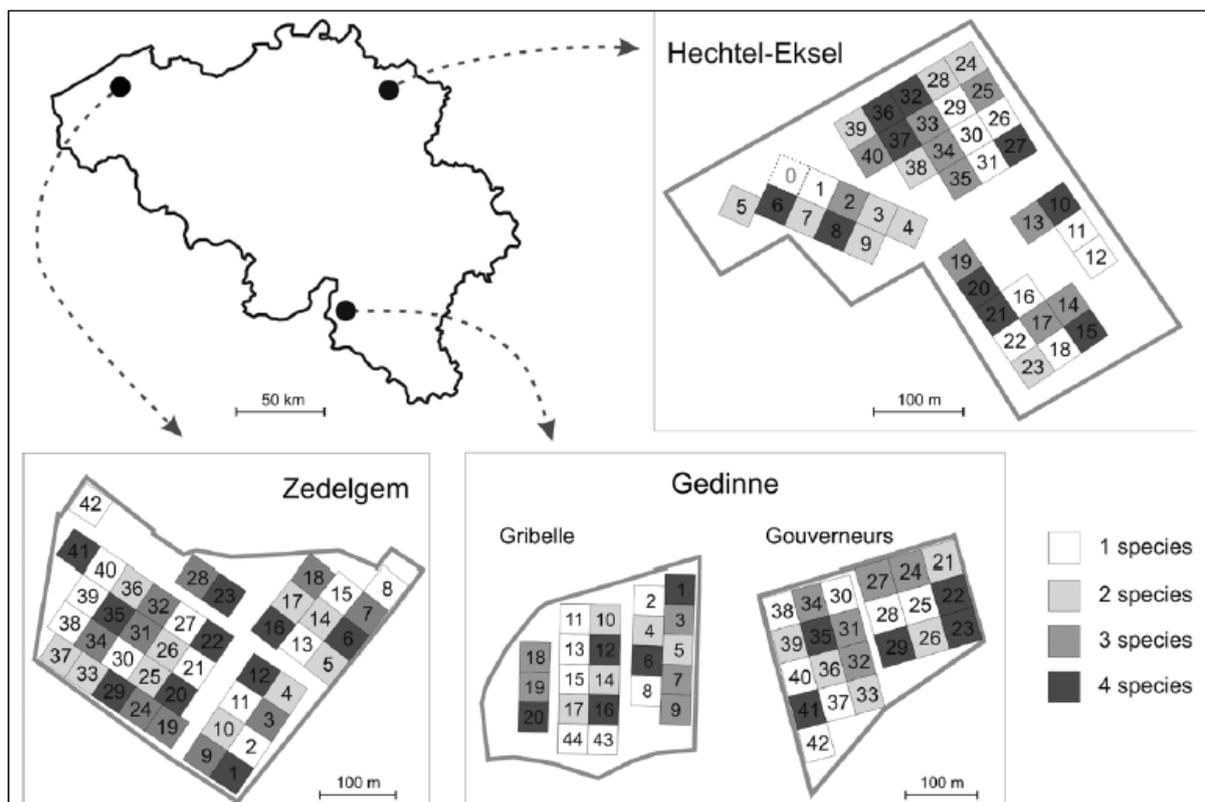

Figure 2-1 The three FORBIO sites situated on the map of Belgium together with their experimental designs. The colour of each plot indicates the number of species planted in mixture or monoculture (copied from Verheyen et al., 2013).

2.1.1 Hechtel-Eksel

The Hechtel-Eksel site is approximately 8 ha in size and located in the Campine ecoregion on a dry sandy soil (51°10'N 5°19'E, 55-56 m a.s.l.). The region has a mean annual temperature (MAT) of 9.0°C and a mean annual precipitation (MAP) of 799 mm. In late autumn of 2012, in total 23,040 trees were planted in 40 different plots, each with a plot size of 36 m x 36 m. As at each site, the trees were planted on a 1.5 m x 1.5 m grid, resulting here in a density of 576 trees per plot. Plot 0 was left unplanted for spontaneous succession. In the mixed plots, trees of the same species were planted in small patches of 3 x 3 trees, except sometimes at the edges where larger cells were used (Figure 2-2). In plots with three or four species, these 3 x 3 cells were randomly arranged and in plots with two species a checkerboard pattern was used (Verheyen et al., 2013). This design is found in all three sites. The following five different species were planted at the Hechtel-Eksel site: silver birch (*Betula pendula* Roth.), Japanese larch (*Larix kaempferi* Sarg.), Scots pine (*Pinus sylvestris* L.), Douglas fir (*Pseudotsuga menziesii* (Mirb.) Franco) and sessile oak (*Quercus petraea* (Mattuschka) Liebl.). The planted trees originate from the nursery Opdebeeck, located in Putte (Verheyen et al., 2013).

Figure 2-2 Experimental planting design of a two-species mixture plot (no. 4 in Zedelgem). Each tree is represented by a number and the colours indicate the species: silver birch (yellow) and Scots pine (pink)

2.1.2 Zedelgem

The Zedelgem site is situated closer to the North Sea in the Cuesta ecoregion on a sandy to loamy sand soil (51°9'N 3°7'E, 11-16 m a.s.l.). The climate in Zedelgem is a bit milder with lower temperatures in the summer and higher temperatures in the winter (MAT = 9.5°C, MAP = 687 mm). This site, established on former agricultural land in the winter of 2009-2010, is approximately 9.5 ha large. At each of the 42 m × 42 m plots, 784 trees were planted, resulting in a total of 32,810 trees divided over the 42 plots. Again, five different species were used in mixture or monoculture: silver birch, common beech (*Fagus sylvatica* L.), Scots pine, pedunculate oak (*Quercus robur* L.) and small-leaved lime (*Tilia cordata* Mill.). In half of the plots the same provenance, i.e. Vekedelle West, of pedunculate oak was planted. In plots with numbers 21 to 42, a mixture of three different provenances was used. This was done to be able to evaluate the effect of genetic diversity on forest biodiversity and ecosystem functioning (Verheyen et al., 2013).

2.1.3 Gedinne

The Gedinne site is situated in the Ardennes ecoregion in the southern part of Belgium and divided into two subsites: Gribelle (49°60'N 4°59'E, 367-376 m a.s.l.) and Gouverneurs (49°59'N 4°59'E, 421-426 m a.s.l.). Both the subsites are about 4.5 ha in size and have a moderately dry loam soil. Compared to the other two sites, the climate is colder and wetter (MAT = 6.9°C, MAP = 1021 mm). In early spring of 2010, in total 44 plots were planted at the Gedinne site, 22 at each subsite. Most of the plots have a size of 42 m x 42 m, except for thirteen plots that measure 42 m x 37.5 m, with 700 trees per plot. Following tree species were planted, again in mixture or monoculture: sycamore maple (*Acer pseudoplatanus* L.), common beech, sessile oak, hybrid larch (*Larix x eurolepis* Henry), and Douglas fir. Similar to the Zedelgem site, at half of the plots, three different provenances of common beech were used to assess the genetic diversity (Verheyen et al., 2013).

2.2 Field Data

In this study, no field data was collected, because the planting data were considered as ground truth data and were readily available. For each site, the number of species, the number of trees per species and the total number of trees planted were available per plot. The delineation of the plots in the coordinate reference system (CRS) Belgian Lambert 72 (EPSG:31370) was also available for each site.

2.3 Multispectral Data

2.3.1 Drone and Camera Characteristics

The drone used to perform the flights is a DJI Matrice 210 RTK V2 (Figure 2-3). The drone weighs approximately 4.91 kg, batteries included, and has unfolded the following dimensions: 883 mm x 886 mm x 398 mm (DJI, 2019). It is a multi-rotor drone with four propellers attached to independently driven motors. By changing the speed of different propellers, it can easily turn around its roll, yaw and pitch axis. The two D-RTK antennas allow for more accurate positioning data and ensure a more stable flight because it interferes less with metal objects (DJI, 2019). Through this D-RTK module, a connection can be made with a ground station or an RTK network. The M210 RTK V2 has an advanced power management and is powered by two TB55 Intelligent Flight batteries with a voltage of 22.8 V and a capacity of 7,660 mAh each. With fully charged batteries and no payload, the drone has a maximum flight time of 33 minutes. To fly the drone, the remote controller with a CrystalSky Monitor attached was used (DJI, 2019).

To ensure safety, the M210 RTK V2 contains a built-in DJI AirSense that automatically gives an alert of aircraft nearby on the CrystalSky Monitor. Also, when the drone loses connection with the remote controller or the battery is low, it will automatically return to the last recorded Home Point and trigger the landing protection. The landing protection will check if the ground is suitable for landing and the pilot can still alter the orientation with the remote controller to ensure a perfect landing (DJI, 2019).

5. MicaSense Altum sensor
6. Landing gears

Figure 2-3 Image of used DJI Matrice 210 RTK V2 drone equipped with the Micasense Altum sensor (Van den Boer, M., 2021).

A Micasense Altum sensor was attached to the M210 RTK V2 (Figure 2-3). This is a multispectral sensor that captures six different bands (red, green, blue, red edge, near-infrared and thermal) with a high spatial resolution (Figure 2-4). The sensor stores files for each band in a 16-bit TIFF with a resolution of 2064 x 1544 pixels except for the thermal band which has a lower resolution of 160 x 120 pixels (Micasense Inc., 2021). At a flying height of 120 m, the GSD of the thermal band and the five other bands are respectively 5.82 cm and 81 cm. The Micasense Altum sensor is also integrated with a Downwelling Light Sensor 2 (DLS 2) on top of the drone (Figure 2-3). This sensor stores information about the ambient light and sun angle during the flight in the metadata of the image files (Micasense Inc., 2020). That information can be used during processing to correct for changing light conditions as discussed in section 1.2.2.

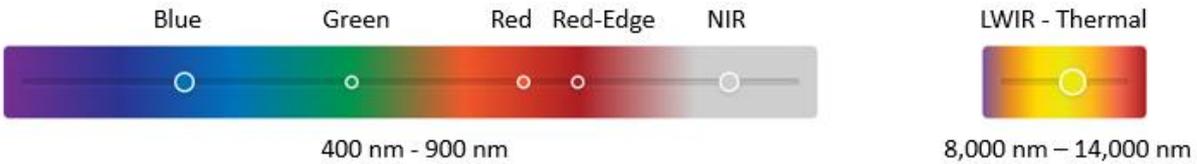

Figure 2-4 The six different bands captured by a Micasense Altum sensor: blue, green, red, red-edge, NIR and thermal (modified from AgEagle Sensor Systems Inc., 2021).

2.3.2 Data Collection

Following sections primarily describe the steps of collecting, processing and analysing drone data during this research. However, it is also intended as a manual that can be used for future research.

Pre-flight Activities

Flying a drone is subject to legal regulations. To be allowed to operate as a pilot in the subcategories OPEN A1 and A3, which cover the conditions of this study, I followed an online training continued by an exam provided by the Belgian Civil Aviation Authority in cooperation with EASA (Figure 2-5). To get the certificate, good knowledge about air traffic safety, restrictions and regulations, limitations to human performances, general knowledge of UAS, privacy, insurance and security is required.

FIRST NAME: **Esther**

LAST NAME: **Tubbax**

BEL-RP-I0y6hqm5wxcy

EXPIRATION DATE: **15.04.2026**

Figure 2-5 Pilot certificate of subcategories OPEN A1 and A3.

Next to the regulations, various other restrictions can apply. The Skeyes drone guide (<https://map.droneguide.be>) was consulted to plan the flight mission dates and times for each site based on the UAS geographical zone statuses. When certain geo zones are active, it can impose a restriction on the flying height and/or time. For most geo zones this is announced well upfront, but for Helicopter Training Areas (HTA) the activation is only communicated one day in advance. The Hechtel-Eksel site is situated near the military basis of Kleine-Brogel, whereby during the day you cannot fly with a UAS because it is inside the controlled airspace area (Figure 2-6). For these flights (performed after the operational hours), the military basis was informed well in advance. In Zedelgem, an HTA was active on the day of the flight mission (Table 2-1).

Figure 2-6 Location of the Hechtel-Eksel FORBIO site inside the Kleine-Brogel controlled airspace area (blue contour). This is an active geozone (EBBL_Kleine-Brogel CTR) where no drone flights can be executed during the day (copied from Skeyes, 2021).

Table 2-1 Duration of the active geo zones at the day of the flight missions at each FORBIO site (only the ones applicable to drone flights, that have a relatively low flight height < 60 m).

| Site | Date | Active geo zone | Duration |
|---------------|------------|------------------------|---------------|
| Hechtel-Eksel | 20/07/2021 | EBBL_Kleine-Brogel CTR | 06:30 – 17:30 |
| Zedelgem | 25/08/2021 | HTA10A | 09:00 – 12:30 |
| | | HTA10A | 13:30 – 16:00 |
| Gedinne | 26/08/2021 | / | / |

Besides checking the local flying restrictions, weather forecasts were also consulted to plan the flight missions. Rain and/or strong winds make missions dangerous because of unclear vision or abrupt changes in the flying path. Additionally, the drone and sensor equipment cannot withstand such harsh conditions. The UAV forecast app was used to check the weather conditions the day of the mission and again right before take-off.

Landowners of each site were asked for permission and they were informed at what exact time the drone flights would take place. Lastly, the details of the mission and the licenced pilots that would execute them were registered in the Drone Service

Application (DSA) Planner provided by Skeyes. Skeyes needs to approve the mission in advance. On the day of the flight, you need to inform them once more via DSA Fly when the drone is in the air, when it is landed and when the drone operation is finished. In that way, they can alert you by phone if you must land immediately due to certain unforeseen circumstances e.g. an aircraft in distress.

Flight planning and execution

The flights were executed on three different days in the summer of 2021 (Table 2-2).

Table 2-2 Data and time of each flight mission in the different FORBIO sites.

| Site | Subsite | Date | Start time |
|---------------|-------------|------------|------------|
| Hechtel-Eksel | | 20/07/2021 | 17:30 |
| Zedelgem | | 25/08/2021 | 12:30 |
| Gedinne | Gribelle | 26/08/2021 | 10:30 |
| | Gouverneurs | 26/08/2021 | 12:50 |

First, different flight missions were configured in the DJI Pilot app (Figure 2-7). This allows the drone to fly autonomously and you can apply the same settings (e.g. flight altitude, % overlap between the images...) for every flight, resulting in better and more consistent data. A polygon of the preferred flight area was drawn by visually marking the border points of the plots on a satellite base map. To limit the flying time and avoid crossing walking paths, the plots were subdivided into blocks for different flight missions (Figure 2-8). Respectively four, five, three and two flight missions were made for the sites in Hechtel-Eksel, Zedelgem, Gribelle and Gouverneurs. In Hechtel-Eksel, plots 24, 28, 32, 36 and 39 were not included in the flight mission plans because the flight would take too long. Plot 8 at the Zedelgem site was not included because of its proximity to a power line.

Figure 2-7 Start screen at DJI Pilot App with two different options: manual flight or mission flight (copied from DJI, 2019).

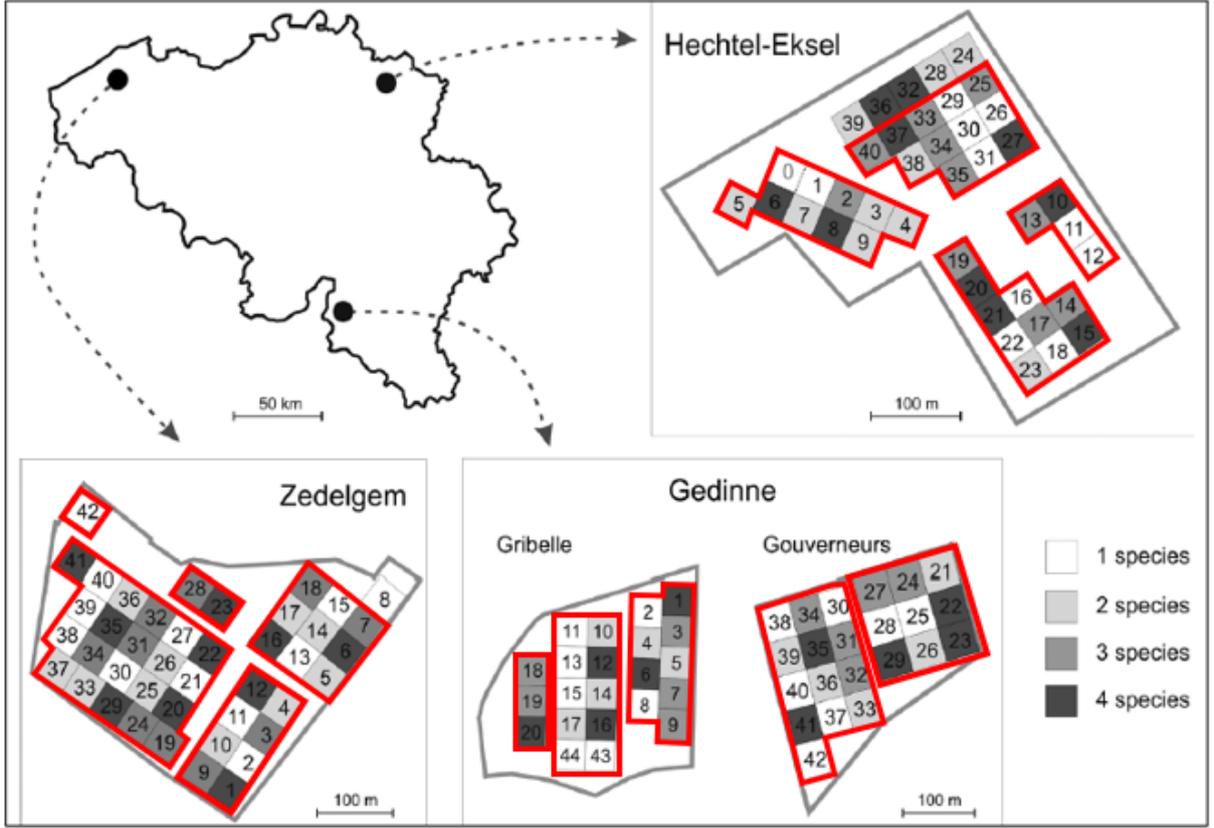

Figure 2-8 The three FORBIO sites situated on the map of Belgium together with their experimental designs. The colour of each plot indicates the number of species planted in mixture or monoculture. The red contours indicate the different flight missions (modified from Verheyen et al., 2013).

For every flight mission, the flight height was set at 40 m above ground level and the front and side overlap both at 75% (Figure 2-9). The MicaSense Altum camera was selected and the photo mode was set at 'distance interval shot' in order to have consistently a photo taken at the same distance.

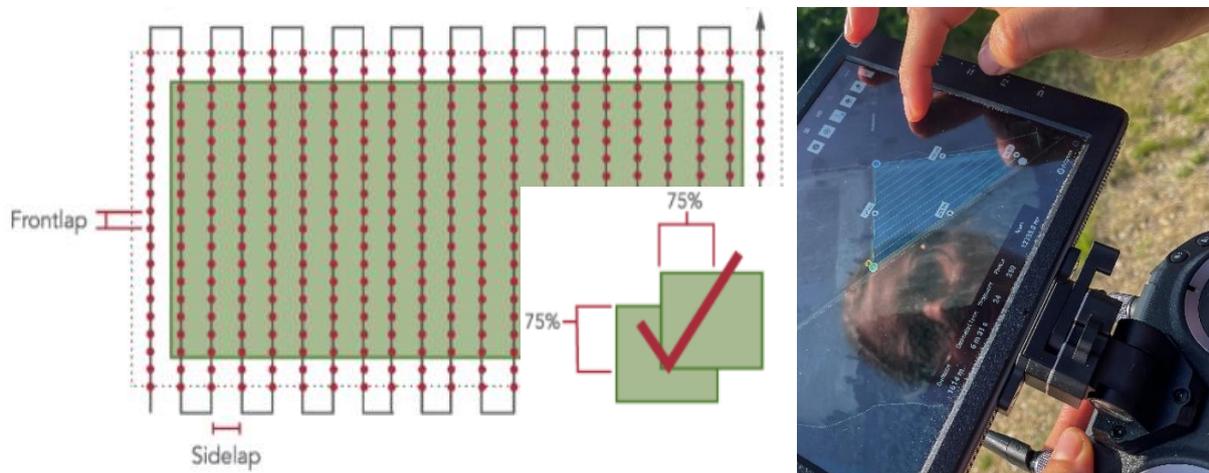

Figure 2-9 Visualisation of front and side overlap of 75% in a flight mission plan: left theoretical, right on the field (AgEagle Sensor Systems Inc., 2021; Van den Boer, M., 2021).

After the flight missions were made and saved, a proper take-off/landing point was chosen. It needs to be a flat surface, clear of objects where a good view over the flight path is ensured (Figure 2-10). Next, the drone compass was calibrated by turning the drone around all its six axes as indicated on the Aircraft Status Bar in the DJI Pilot app. At the sites in Flanders (Hechtel-Eksel and Zedelgem) connection was made with the mobile RTK-network FLEPOS and at the Gedinne site with the mobile RTK-network Walcors. By connecting via the DJI Pilot app to these networks, more accurate positioning is established, which will ensure a more stable flight.

Figure 2-10 Photo of the take-off/landing point at the Hechtel-Eksel FORBIO site (Van den Boer, M., 2021).

Then it was checked if the drone was fully equipped and ready to take off:

- Sufficient battery level of the remote controller, Intelligent Flight Batteries and display device depending on flight time
- D-RTK antennas locked properly
- Propellers having free rotation
- MicaSense Altum sensor
 - o Protective cover removed
 - o MicroSD card inserted
 - o Connected with DLS 2
- DJI Pilot app having a connection with the drone

Lastly, right before and after every flight, a reflection calibration was executed. This was done by capturing an image of the Calibrated Reflectance Panel (CRP) by holding the drone about 1 m above it while making sure it is not covered by any shadow of a person or object nearby (Figure 2-11). In the case that no DLS 2 is connected to the drone's camera, these images can be used during processing to correct for the incident light conditions at the time of the flight. However, this radiometric correction assumes a rather constant reflectance during the flight because no real-time atmospheric conditions are measured. Therefore, it is less accurate than the DLS 2 where the images of the CRP are used to calibrate the DLS 2. Integrating CRP and DLS 2 significantly improves the radiometric correction for changing atmospheric conditions (C. Wang, 2021).

Figure 2-11 Calibrated Reflectance Panel to correct for incident light conditions at the time of the flight mission (copied from AgEagle Sensor Systems Inc., 2021)

During the flight, it was important to make sure the drone was always in the visible line of sight (VLOS) of the pilot. If not, when the drone was beyond the visible line of sight (BVLOS), the pilot was always in contact with someone that had the drone in VLOS.

This is needed to make sure the pilot can take over the drone at any time. Because of the same reason, the operating pilot could not be disturbed during the flight by passers-by. Therefore, a fluorescent vest with the inscription 'Pilot DO NOT DISTURB' was worn during the flights (Figure 2-12).

Figure 2-12 Photo of drone pilot with fluorescent vest with the inscription 'Pilot DO NOT DISTURB' (Van den Boer, M., 2021).

After the flight, the reflection calibration was executed again as explained before and - when necessary - Skeyes was informed via the DSA Fly that we landed again. After inspection, the drone was folded and stored. The data was uploaded immediately via the microSD card to an external disk. At home, all the batteries were recharged to be fully operational for the next flight.

2.4 Preprocessing

2.4.1 Preprocessing using MAPEO

First, multiple flights were pre-processed with PIX4Dmapper. However, this photogrammetry software had difficulties processing the large datasets on computers with limiting computing power, resulting in calibration problems and poor imaging. The key point image scale, the number of key points and the calibration method were adapted trying to improve the processing, but it did not result in the desired quality.

Therefore, the MAPEO services of VITO were used for the image pre-processing. Each flight mission is processed separately in MAPEO Field Software 1.0.5 using the following steps. To upload a new mission, first, the right mission profile 'Micasense Altum' was selected out of a list with different pre-programmed sensors (Figure 2-13). For the data quality check later, the default settings were used. If the used sensor is not present in the dropdown menu, the characteristics can be added manually.

Mission Creation - Step 1/3 : Select mission profile

Profile:

Mission profile

Custom focal length mm

Figure 2-13 First step of mission creation to pre-process drone data with MAPEO Field Software. A mission profile can be selected out of a dropdown menu or can be manually added.

Next, the mission data was uploaded (Figure 2-14). This includes a folder with all the images of the mission, together with the before and after flight images of the Calibrated Reflectance Panel, and a kml-file of the region of interest (ROI). Then, the first and last images of the flight path were selected on the map and the flight height was set at 40 m. As result, the flight lines were drawn automatically (Figure 2-15). The next step was validating the overlap of the images inside the ROI: the bluer the colour, the better the result (Figure 2-15). In this step, ground control points (GCP) could be added if measured in the field, which was not the case in this research. As the last step of the mission creation, the flight description was added (Figure 2-16). Only the mission's name needed to be filled in because the other fields were pre-filled automatically since we used a pre-programmed sensor.

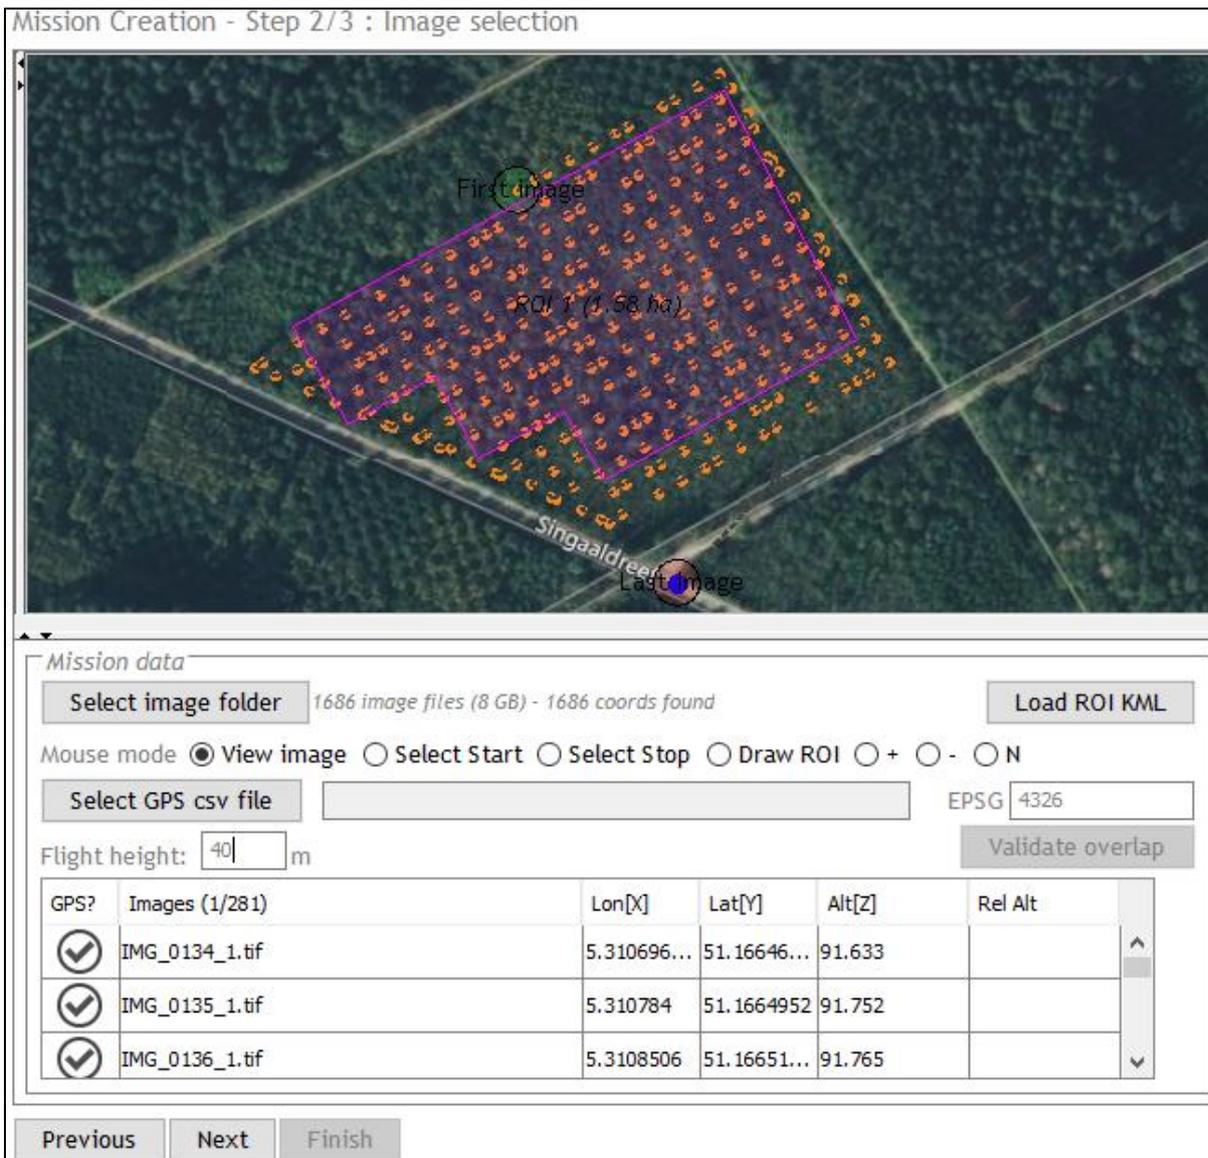

Figure 2-14 Second step of mission creation to pre-process drone data with MAPEO Field Software. Drone images can be uploaded by 'select image folder' and the right flight height needs to be given.

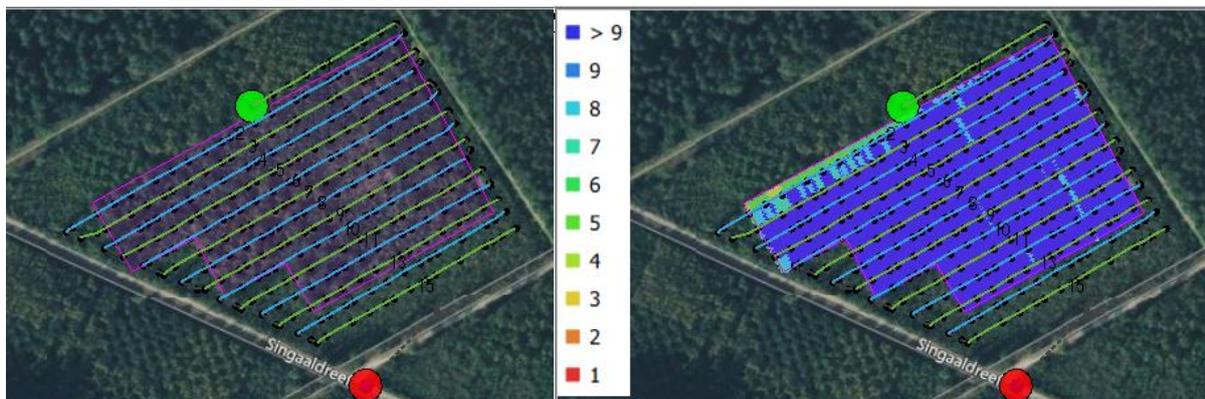

Figure 2-15 Second step of mission creation to pre-process drone data with MAPEO Field Software. The first and last images need to be selected whereby the flight lines are drawn automatically (left). By validating overlap inside the region of interest, an overview of the overlap quality is given in a colour scale (right): the bluer, the better.

Figure 2-16 Third and last step of mission creation to pre-process drone data with MAPEO Field Software. In this step the flight description needs to be given. When a pre-programmed sensor is used only the mission name should be filled in.

Before uploading the mission for pre-processing, the quality checks were consulted (Figure 2-17). At this point, input data could be adapted to improve the quality depending on the type of error. In this research, no improvements were possible with the available data. However, if for example some images do not have valid coordinates, these images could be removed to improve the processing quality. Next, the data was uploaded for standardized photogrammetric and radiometric processing. As output, a multiband raster image, a digital terrain model (DTM), a digital surface model (DSM) and an NDVI raster image were created per flight mission.

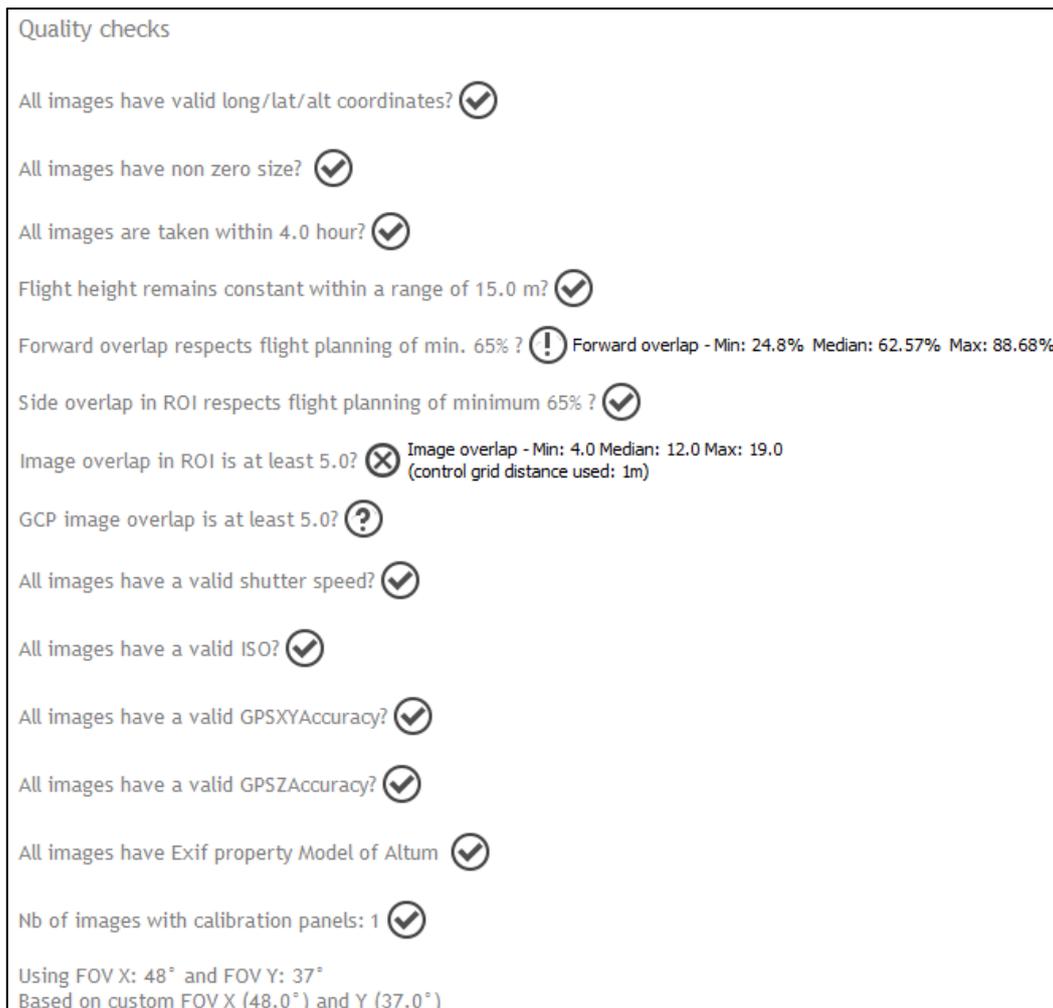

Figure 2-17 Quality check step to pre-process drone data with MAPEO Field Software. A check mark indicates that the quality is good, an exclamation marks points out there might be a problem and a cross mark shows that there is a problem.

2.4.2 Preprocessing Raster Data per Plot

All analyses were performed using R version 4.2.1 (R Core Team, 2022). A schematic overview of the steps to extract the raster data per plot is given in Figure 2-18 and explained here in more detail. First, the perimeter of each site (shapefile) was imported and transformed from Belgian Lambert 72 (EPSG:31370) to World Geodetic System 1984 (WGS 84) with the sf package (Pebesma, 2018). Using the same package, the plot sizes were reduced by 4 m at each side to minimize edge effects and correct slight positioning errors in the drone data. For example, a plot size of 42 m x 42 m was reduced to 34 m x 34 m. Before further processing, the data was reviewed by removing some plots. The data of plots 5 and 9 in Hechtel-Eksel and plot 21 in Gouverneurs were not used because after MAPEO pre-processing, in more than half of these plot sizes data was missing due to some malfunctioning during data capturing or processing.

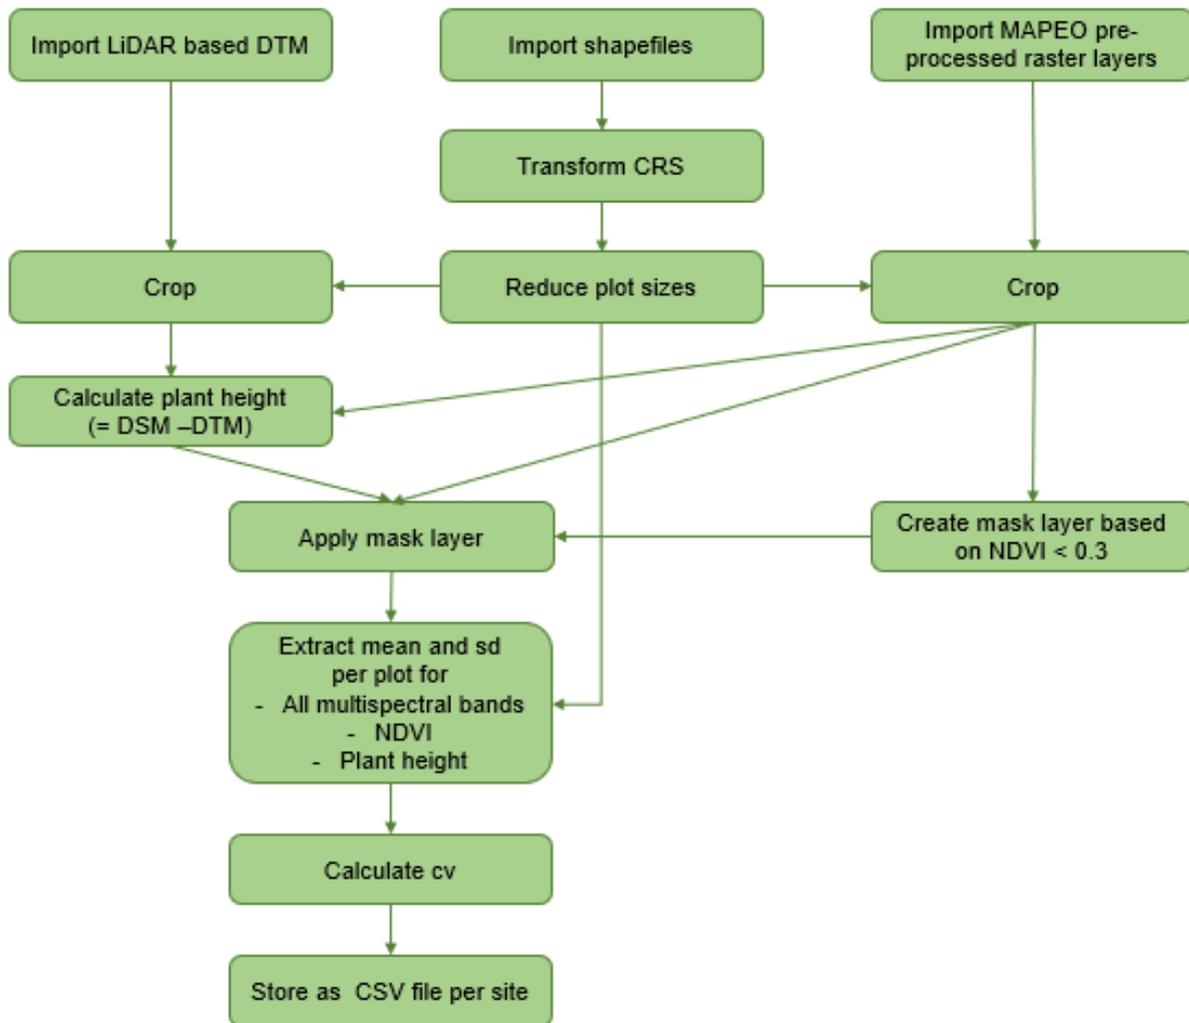

Figure 2-18 Schematic overview of the steps followed to extract the mean, standard deviation (SD) and correlation of variation (CV) of the different raster layers per plot in each FORBIO site.

Next, DTMs of Flanders and Wallonia were requested and downloaded (Agentschap Digitaal Vlaanderen, 2014; Service public de Wallonie, 2014). Both these DTMs are a result of LiDAR data acquisitions from a period between 2013 and 2014. The ground resolution of both datasets is 1 m and their CRS is Belgian Lambert 72 (EPSG:31370). These data were used instead of the DTM results from the MAPEO processing because they have higher accuracy.

All following steps were applied to the data of each flight mission separately. The MAPEO pre-processed raster layers (multiband rasters, NDVI rasters, DSM rasters) and the DTM rasters of Flanders and Wallonia were imported in R using the raster package (Hijmans, 2022a). Then they were cropped to the extent of the corresponding site. With the dplyr package, the plots reduced in size were masked out the resulting raster datasets to only keep information from inside the plots (Wickham et al., 2022).

Based on the NDVI, a mask layer was created to mask out pixels with no vegetation or dead vegetation inside the plots. All pixels with an NDVI value larger than 0.3 were given the value one and the other pixels a value of zero. This boundary was chosen because healthy vegetation generally has an NDVI larger than 0.3 (Jones & Vaughan, 2010). The created mask layers were multiplied with all the other raster layers and then the zero values were replaced by NA-values. All resulting raster datasets were exported to TIFF files.

The next step was to extract a mean value and the standard deviation (sd) for each of the variables per plot. This was done by first importing the masked layers using the terra package (Hijmans, 2022b). With the exactextractr package, the mean and sd were extracted per plot per flight mission (Daniel Baston, 2022). Next, the correlation of variance (cv) was calculated per plot for all the reflectance bands, the NDVI and the plant height by dividing the sd by the mean.

2.5 Species Richness and Productivity Calculation

The alpha diversity in each plot was calculated based on the number of trees per species present in each plot. Examples of some popular indices to calculate alpha diversity are the Shannon index, Simpson index, species richness, and Rao quadratic entropy index (Leinster & Cobbold, 2012). However, effective numbers of species (ENS) are recently more used as a measure because they make diversity comparisons and percentage changes meaningful (Leinster & Cobbold, 2012). Therefore, this last index was calculated as measure of alpha diversity. As the evenness for all plots equals one, both ENS_{Simpson} and ENS_{Shannon} are equal to the species richness (SR). Therefore, I only consider SR in what follows.

To calculate the plant height, the DTM raster layers were subtracted from the DSM raster layers to generate a canopy height model. The plant height was corrected by lowering it by 39 m for all plots and sites. An error in the MAPEO pre-processed DSM was observed, which resulted in a plant height much higher than observed during the flights. The average drone-based calculated plant height per plot in Hechtel-Eksel was compared with the average in situ height measurements per plot in Hechtel-Eksel from 2019. This difference was assumed to be an approximation of the error and therefore subtracted from the plant height in each plot at the different sites. The cv was recalculated as well with the new mean plant height.

The mean plant height per plot was considered as proxy for forest productivity. Plant height is generally a good indicator of tree productivity in the first years, mainly in dense plantations, because height growth is still more prominent than diameter growth. The net diversity effect (NDE) in each mixture plot per site was calculated as well (Loreau M. & Hector. A., 2001). For this analysis the sites were evaluated separately, because of the different soil and climatological conditions. The mean plant height of every species in monoculture (PH_i) was extracted from the data. Then, the expected plant height (PH_{exp}) in a mixture was calculated based on the proportion of the different species (p_i) present in the plot using equation 2.1. Finally, to evaluate the overyielding, the NDE was calculated by comparing the expected plant height with the observed plant height (PH_o ; equation 2.2; Van de Peer et al., 2018). A positive NDE will be obtained when high-productive species dominate in the mixed plots (positive selection) or when species perform better in mixture than in monoculture because of positive complementarity (Loreau M. & Hector. A., 2001).

$$PH_{exp} = \sum_i^N p_i \times PH_i \quad (2.1)$$

$$NDE = PH_o - PH_{exp} \quad (2.2)$$

2.6 Data Analysis

Different models to predict the alpha diversity and the productivity were made and evaluated. To determine which variables should be used in the model to predict the SR and plant height, the correlation between all the different variables was evaluated (Appendix XVI). When different variables had a correlation higher than 0.7, only one of them was used. Next, the correlation between the SR and the remaining variables was assessed. The variables with a correlation lower than 0.1 were not used either, because it would only overcomplicate the model. The same variable selection was applied for the plant height models. All data was standardized using the vegan package (Oksanen et al., 2020).

Four different models were made to predict SR: one with only spectral data (formula 2.3), one with only spectral heterogeneity data (formula 2.4), one with only plant height data (formula 2.5) and the last one combining spectral and plant height data (formula 2.6).

$$SR \sim RE + Blue_{cv} + NIR_{cv} + NDVI_{cv} + (1 | site) + (1 | field) \quad (2.3)$$

$$SR \sim Blue_{cv} + NIR_{cv} + NDVI_{cv} + (1 | site) + (1 | field) \quad (2.4)$$

$$SR \sim PH_{Osd} + (1 | site) + (1 | field) \quad (2.5)$$

$$SR \sim RE + Blue_{cv} + NIR_{cv} + NDVI_{cv} + PH_{Osd} + (1 | site) + (1 | field) \quad (2.6)$$

A mixed Poisson regression model was used because the response variable in question (species richness) is count data. Both the site and the flight mission were included as random effects to take the hierarchical nature of the data into account. To start, this was done using the lme4 package (Bates et al., 2015). However, that always resulted in singularity problems even when simplifying the models. When a fit is singular, a model result is achieved but there is a high chance that it is a false positive. As a solution, Bayesian modelling was applied using the brms package to fit the abovementioned models (Bürkner, 2017). The number of cores and the number of Markov chains were both set at two and the total number of iterations per chain was set at 30,000. After the fit, it was checked if model convergence was achieved: Rhat needs to equal one and the effective sample size needs to be large enough (>1,000) for each parameter.

The same modelling method as described above was used to model the productivity. On the one hand, the observed plant height was modelled in function of spectral data (formula 2.7) and on the other hand in function of species richness (formula 2.8). Since the plant height is not count data, a Gaussian distribution was used instead of a Poisson distribution.

$$PH_O \sim Blue + RE + NIR_{cv} + NDVI + (1 | site) + (1 | field) \quad (2.7)$$

$$PH_O \sim SR + (1 | site) + (1 | field) \quad (2.8)$$

After the fits, the models were evaluated using the DHARMA package (Hartig, 2022). In the case of overdispersion, which was only applicable for the models to predict SR, the model fit was repeated but with a negative binomial distribution instead of a Poisson distribution. Finally, the results of the complex mixed models were also compared with more simple (generalised) linear models to see if the coefficient estimates were similar.

The Kruskal-Wallis test with a significance level of 5% was performed per site to determine if there was a significant difference in NDE between plots with a different SR. This non-parametric test was used because the assumptions of normality were not met since the observations were not independent. When a significant difference was observed, the Dunn's post hoc test with Benjamini-Hochberg adjustment was conducted using the FSA package to identify which SR groups were significantly different from one another (Ogle et al., 2021). The results were visualised with boxplots using the rcompanion package to add letters on top of the boxplots to show significant differences (Mangiafico, 2021).

3 Results

3.1 MAPEO-preprocessed Data

The results across the different flight missions all appear to be similar over the four sites, therefore the results of only one randomly chosen flight mission will be presented here. The chosen flight mission is situated in Zedelgem and contains plots 5 – 7 and plots 13 – 18 (Figure 3-1). The results of the other flight missions can be found in appendix.

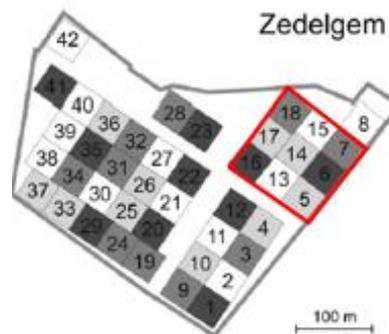

Figure 3-1 A graphic representation of the FORBIO site in Zedelgem. The red contour line indicates the flight mission for which results will be presented (modified from Verheyen et al., 2013).

After MAPEO pre-processing, a reflection raster with seven different bands is obtained: blue, green, red, red edge, near-infrared, longwave infrared and alpha. The range of each of the bands is between 0 and 65535 (Figure 3-3). This is because the alpha band, used for image visualisation has a value of 65535 and the other bands are not yet corrected for it. The terrain height varies between 50 and 65 m and the surface height between 50 and 75 m (Figure 3-2). The NDVI appears to be relatively uniform and has values between 0 and 1 (Figure 3-4).

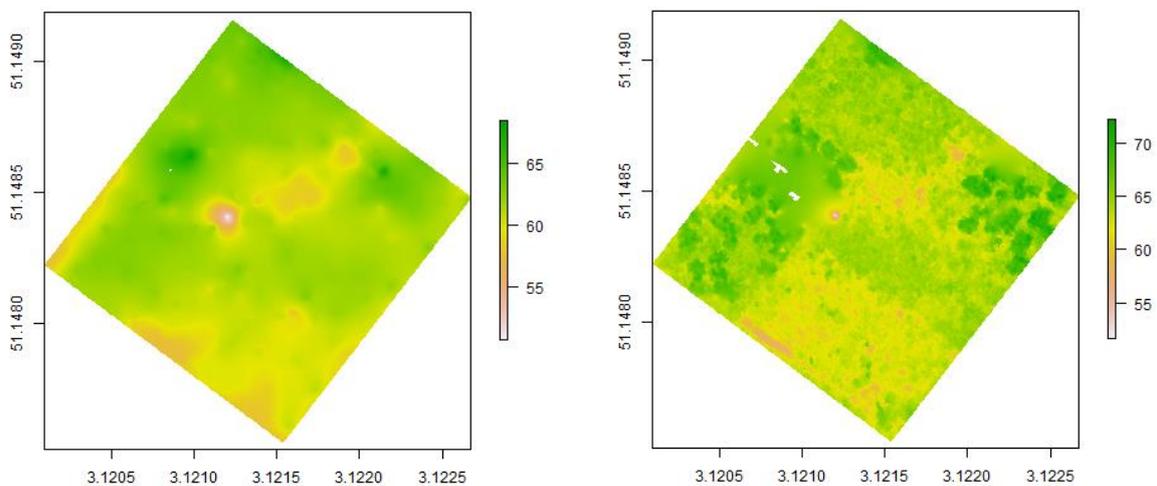

Figure 3-2 DTM (left) and DSM (right) in meters of one show case flight mission at the FORBIO site in Zedelgem.

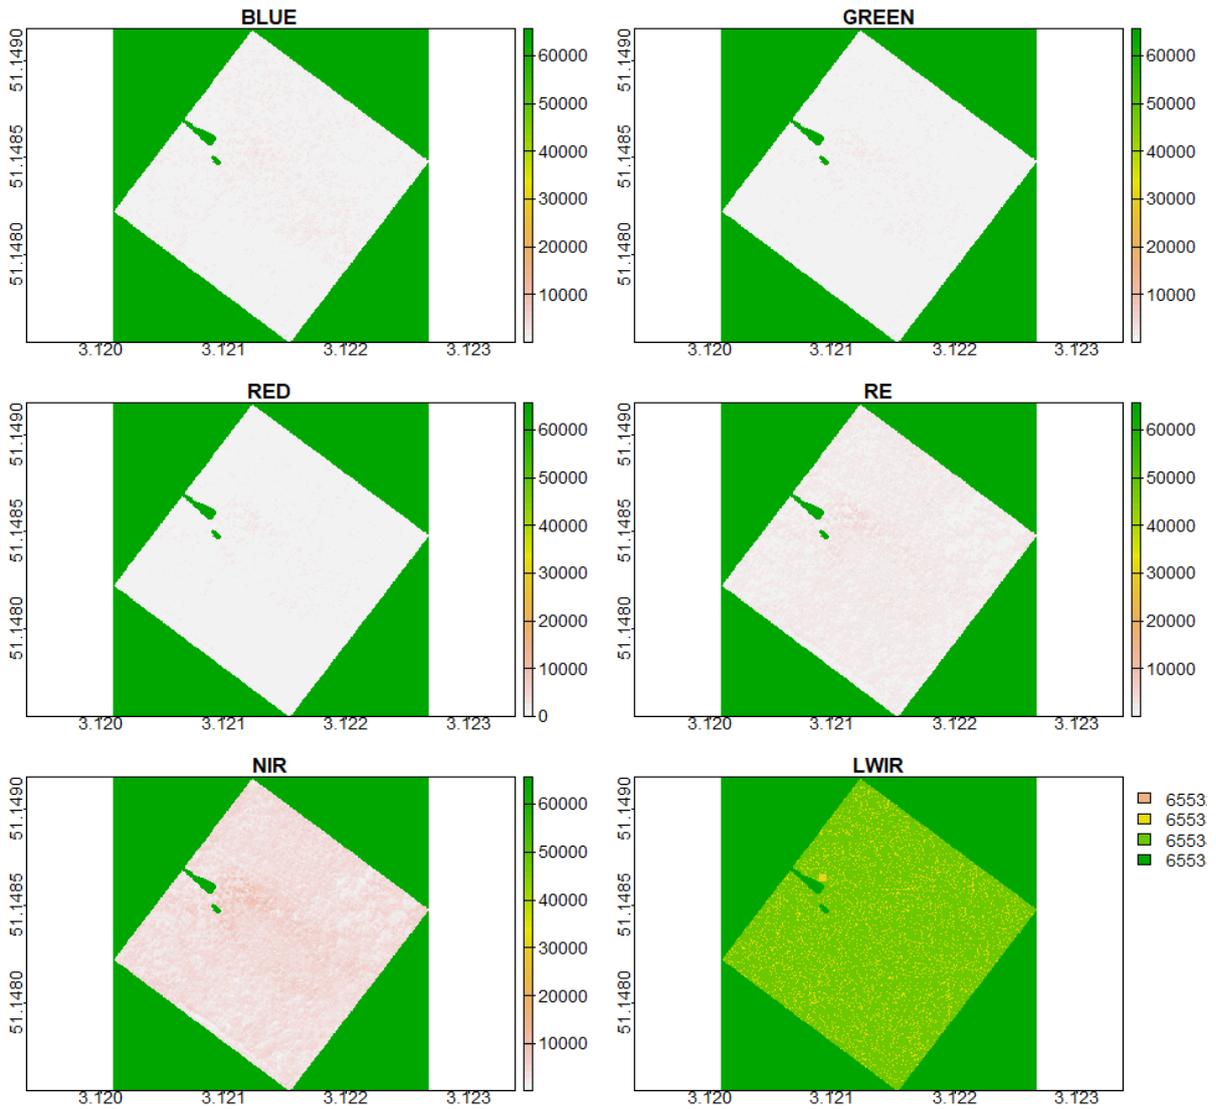

Figure 3-3 Reflectance data of one show case flight mission at the FORBIO site in Zedelgem. Six different bands are presented from left to right: blue, green, red, red edge (RE), near-infrared (NIR), longwave infrared (LWIR).

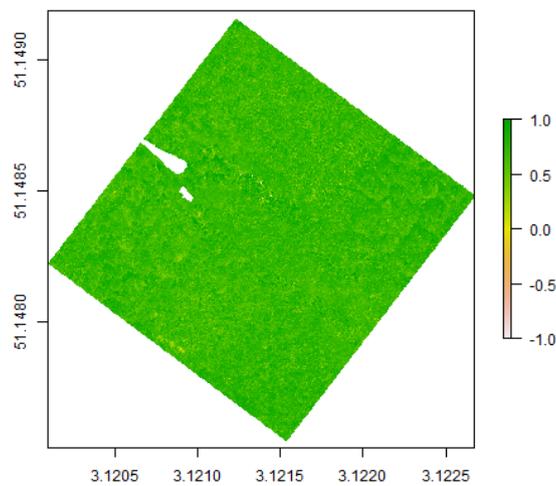

Figure 3-4 NDVI of one show case flight mission at the FORBIO site in Zedelgem.

3.2 Extracted Raster Data per Plot

The new plot sizes of the FORBIO site in Zedelgem are 34 m x 34 m compared to the original plot sizes of 42 m x 42 m (Figure 3-5). Applying these new plots to the DTM of Flanders, results in terrain height between 11 m and 16 m, with higher altitudes in the northeast and lower in the west part of the site (Figure 3-6). The mask layer derived from the NDVI, has zero values for one gap at the west side and some small spots spread over the different plots (Figure 3-7).

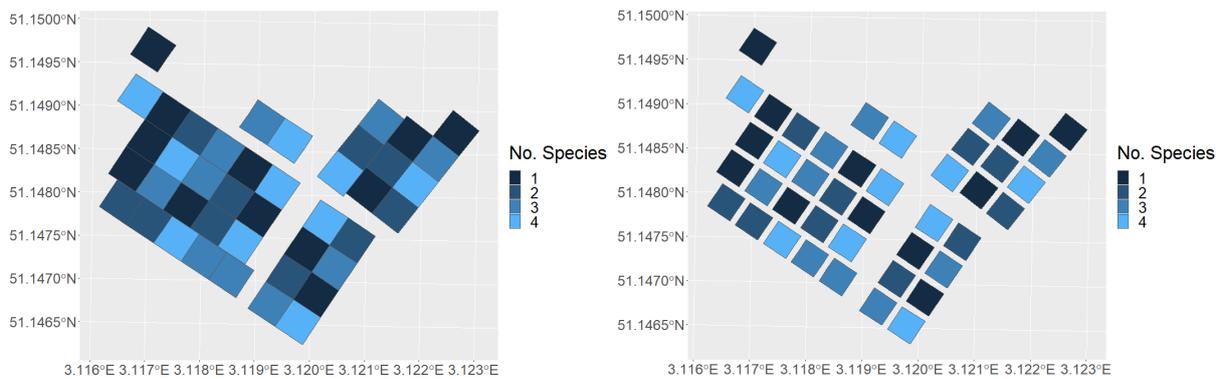

Figure 3-5 Plots of the FORBIO experiment in Zedelgem with the colour representing the number of species. On the left the original plot sizes are given and on the right the plot sizes reduced by 4 m at each side.

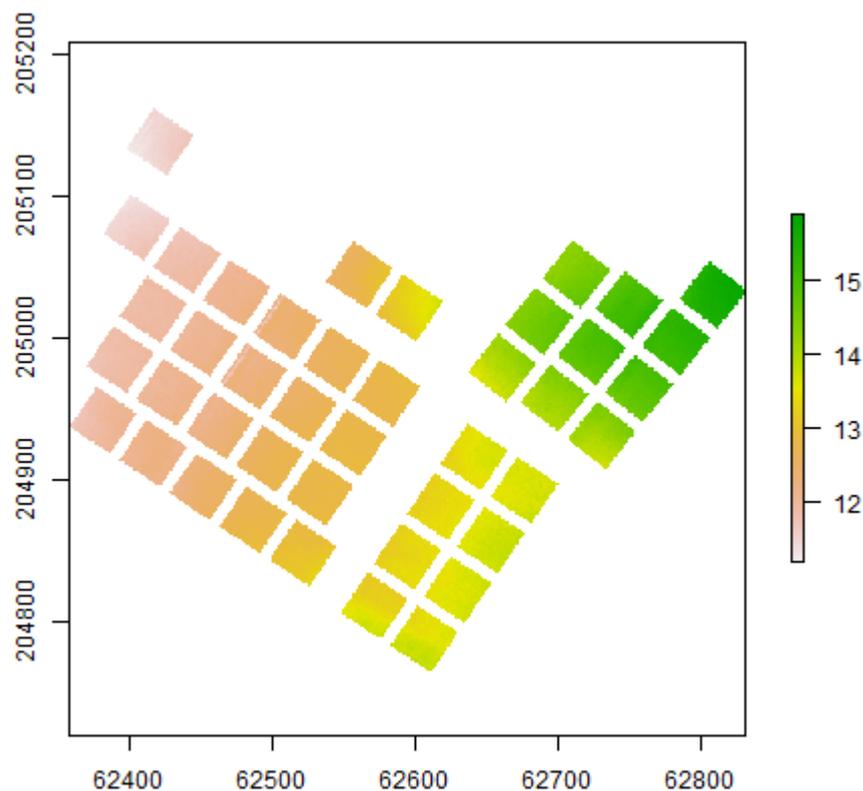

Figure 3-6 DTM in meters of the FORBIO site in Zedelgem.

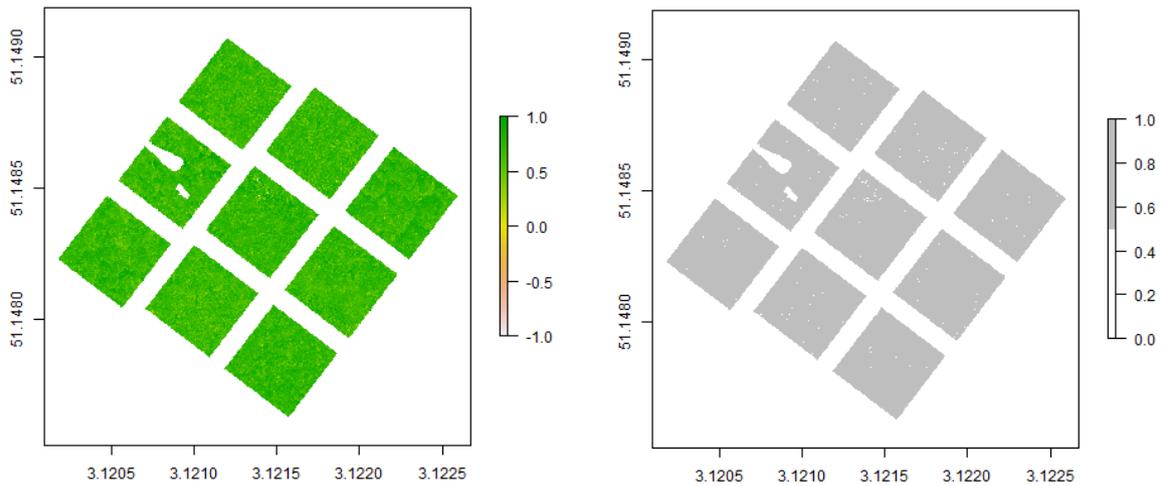

Figure 3-7 A mask layer (right) derived from the NDVI layer (left) where values are lower than 0.3. This is the result of one show case flight mission at the FORBIO site in Zedelgem.

The plant height derived from the DTM of Flanders and the MAPEO DSM ranges between 45 m and 55 m (Figure 3-8). The corrected plant height therefore ranges between 6 and 16 m. After clipping with the reduced plot sizes, correcting for the alpha band and applying the mask layer, more clear variations in the different reflectance bands are visible (Figure 3-9).

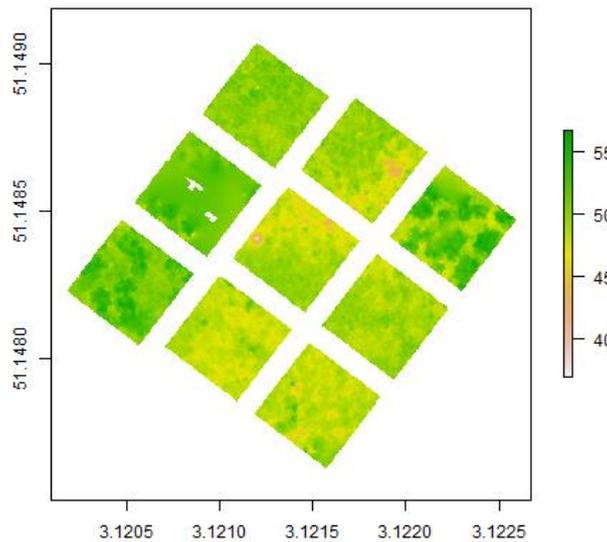

Figure 3-8 Plant height in meters of one show case flight mission at the FORBIO site in Zedelgem.

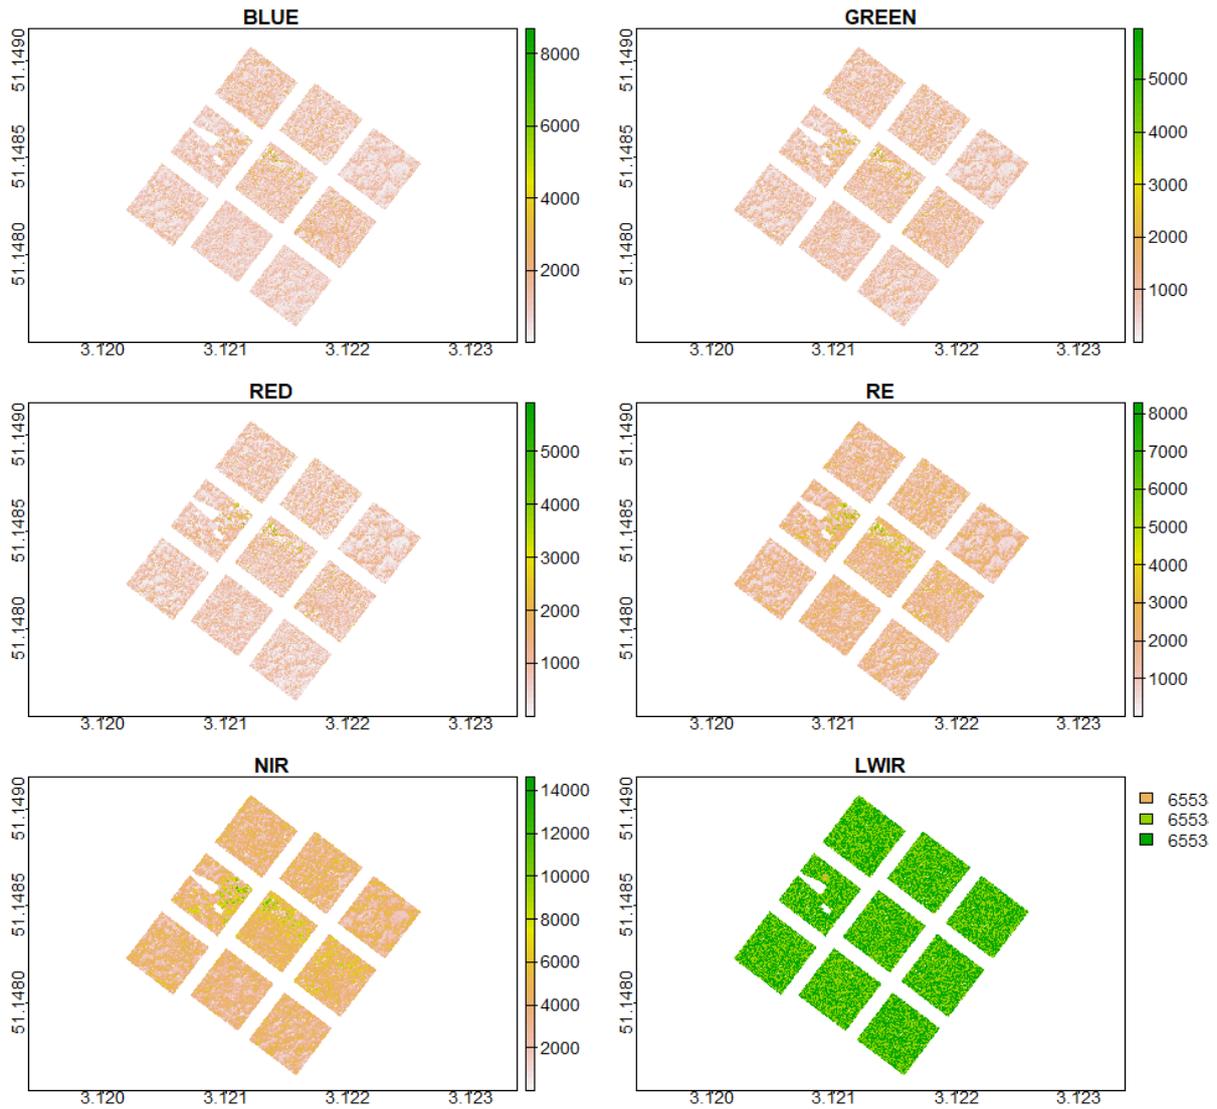

Figure 3-9 Reflectance data after clipping with size-reduced plots and correcting for the alpha band. This is the result of one show case flight mission at the FORBIO site in Zedelgem. Six different bands are presented from left to right: blue, green, red, red edge, near-infrared, longwave infrared.

The mean of the red, green and blue reflectance bands per plot range between 500 and 1200 with an sd between 400 and 900 (Table 3-1). The RE and the NIR generally have a higher mean per plot and therefore a higher sd as well. For every plot, the LWIR has a value of 65535 ± 0.5 .

Table 3-1 For the plots of one show case flight mission at the FORBIO site in Zedelgem, represented by plot ID, the number of species and the number of trees per species are given.

| Plot ID | No. species | No. common beech | No. pedunculate oak | No. silver birch | No. small-leaved lime | No. Scots pine | Total No. trees |
|---------|-------------|------------------|---------------------|------------------|-----------------------|----------------|-----------------|
| 5 | 2 | 398 | 0 | 0 | 386 | 0 | 784 |
| 6 | 4 | 189 | 199 | 0 | 204 | 192 | 784 |
| 7 | 3 | 0 | 261 | 259 | 264 | 0 | 784 |
| 13 | 1 | 0 | 0 | 0 | 784 | 0 | 784 |
| 14 | 2 | 384 | 400 | 0 | 0 | 0 | 784 |
| 15 | 1 | 0 | 784 | 0 | 0 | 0 | 784 |
| 16 | 4 | 197 | 192 | 190 | 0 | 205 | 784 |
| 17 | 2 | 0 | 384 | 400 | 0 | 0 | 784 |
| 18 | 3 | 0 | 259 | 0 | 264 | 261 | 784 |

Table 3-2 For the plots of one show case flight mission at the FORBIO site in Zedelgem, represented by plot ID, the mean and standard deviation (sd) of different reflectance bands are given: blue, green, red, red edge (RE), near infrared (NIR) and longwave infrared (LWIR). These values are a result after clipping with the reduced plot sizes, correcting for the alpha band and applying the mask layer to eliminate dead or unhealthy vegetation pixels.

| Plot ID | Blue | Green | Red | RE | NIR | LWIR | Blue sd | Green sd | Red sd | RE sd | NIR sd | LWIR sd |
|---------|------|-------|-----|------|------|-------|---------|----------|--------|-------|--------|---------|
| 5 | 762 | 661 | 563 | 1440 | 3373 | 65535 | 496 | 440 | 406 | 781 | 1331 | 0.50 |
| 6 | 1205 | 877 | 784 | 1627 | 4190 | 65535 | 792 | 544 | 531 | 859 | 1558 | 0.50 |

3.3 Species Richness and Productivity Models

The model to predict SR based on spectral data has a coefficient of determination (R^2) value of 0.16 and the only significant variable is the intercept. The intercepts also significantly differ across the different sites and flight missions (Table 3-4). When only using spectral heterogeneity data, i.e. cv of different bands, the R^2 -value of the model decreases to 0.13. Again, nothing but the intercept is significant (Table 3-4). The model to predict SR based on the variation in plant height has a higher R^2 -value of 0.26. Besides the intercept, the sd of the observed plant height is significant as well and has an effect size of 0.22 (Table 3-4). The combined model has the highest R^2 -values of the models to predict the species richness (R^2 -value = 0.33). Only the intercept and the sd of the observed plant height with an effect size of 0.21 are significant (Table 3-4).

Table 3-4 Results of Bayesian generalised linear models with negative binomial distribution to predict the species richness. The estimate, estimate error, lower 95% credible interval, upper 95% credible interval and Rhat are given per variable.

| Spectral model | | | | | | |
|-----------------------------------|--------------------|----------|-------|----------|----------|------|
| | | Estimate | Error | l-95% CI | u-95% CI | Rhat |

| | PH ₀ sd | 0.21 | 0.06 | 0.09 | 0.34 | 1.00 |

The model to predict the plant height based on spectral data has an R²-value of 0.72. Two different variables are significant: the RE band and the NDVI, with effect sizes of respectively -0.42 and 0.43 (Table 3-5). When modelling the plant height solely based on SR, the R²-value decreases to 0.69. The SR is the only significant variable and has an effect size of 0.11 (Table 3-5).

Table 3-5 Results of Bayesian linear models with Gaussian distribution to predict the plant height. The estimate, estimate error, lower 95% credible interval, upper 95% credible interval and Rhat are given per variable.

| Spectral model | | | | | | |
|-----------------------------------|----------------|----------|-------|----------|----------|------|
| | | Estimate | Error | l-95% CI | u-95% CI | Rhat |
| Group level effects: sd intercept | Flight mission | 0.37 | 0.18 | 0.09 | 0.79 | 1.00 |
| | Site | 1.48 | 0.80 | 0.57 | 3.53 | 1.00 |
| Population level effects | Intercept | 0.07 | 0.75 | -1.45 | 1.60 | 1.00 |
| | Blue | 0.17 | 0.13 | -0.09 | 0.42 | 1.00 |
| | RE | -0.42 | 0.15 | -0.72 | -0.13 | 1.00 |
| | NIR cv | 0.14 | 0.12 | -0.09 | 0.37 | 1.00 |
| | NDVI | 0.43 | 0.19 | 0.02 | 0.61 | 1.00 |
| Species Richness model | | | | | | |
| | | Estimate | Error | l-95% CI | u-95% CI | Rhat |
| Group level effects: sd intercept | Flight mission | 0.29 | 0.13 | 0.07 | 0.59 | 1.00 |
| | Site | 1.30 | 0.74 | 0.51 | 3.20 | 1.00 |
| Population level effects | Intercept | -0.22 | 0.68 | -1.58 | 1.17 | 1.00 |
| | SR | 0.11 | 0.05 | 0.02 | 0.20 | 1.00 |

In 80% of all the mixed plots, a positive NDE is observed. When looking per site, this percentage is higher in Zedelgem (97%) and lower in Hechtel-Eksel and Gedinne (70% and 72%). However, the NDE shows no significant difference with increasing SR at the Hechtel-Eksel site (p-value = 0.24) and at the Gedinne site (p-value = 0.28; Figure 3-10). There is more variation present in the Gedinne data set. At the Zedelgem site, the NDE significantly differs between plots with a different SR (p-value < 0.01). Plots with three or four species have a significant higher NDE compared to plots with one species. The NDE in plots with more than one species do not significantly differ from one another (Figure 3-11).

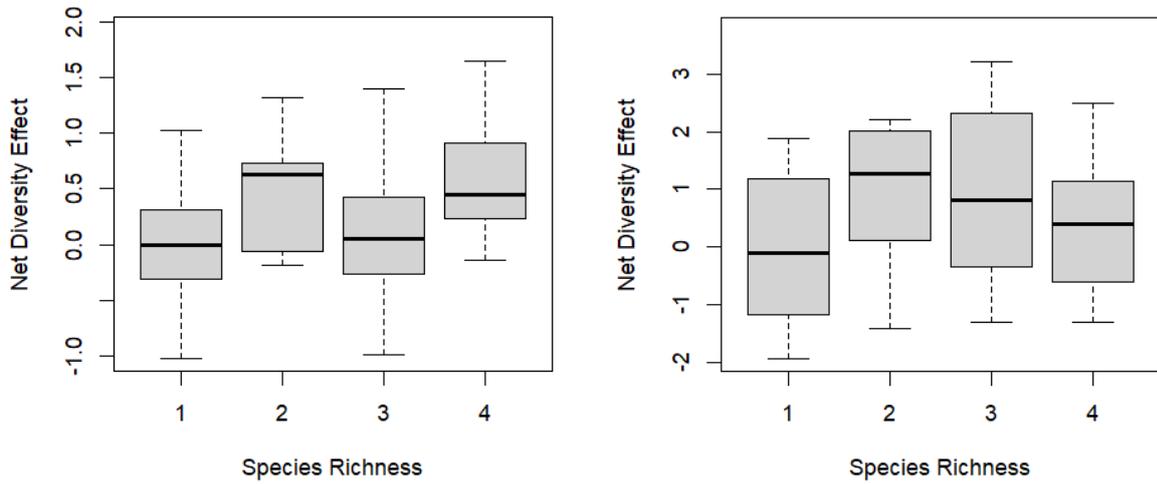

Figure 3-10 Net diversity effect per species richness of the FORBIO site in Hechtel-Eksel (left) and Gedinne (right).

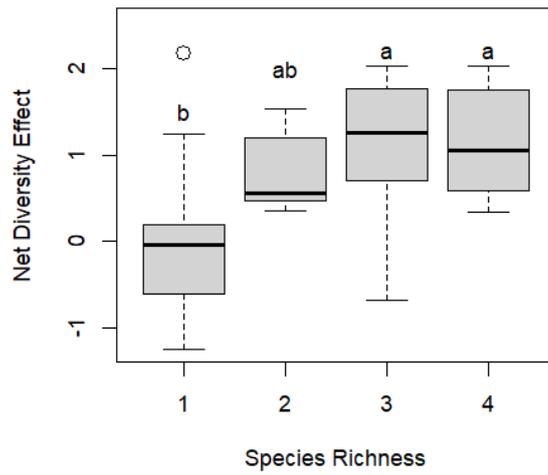

Figure 3-11 Net diversity effect (NE) per species richness (SR) of the FORBIO site in Zedelgem. Different letters above the boxplots show that the SR have a significantly different NDE according to Dunn's post hoc test.

4 Discussion

4.1 Spectral Diversity is a Weak Predictor of Tree Species Diversity

In this study, we tried to predict tree species richness on the one hand and tree productivity on the other hand based on collected multispectral drone data. We evaluated which parameters were best to be included in the models and how they could be improved. A pipeline of the steps of collecting, processing and analysing drone data was documented during this study and possible improvements for future research will be indicated in this discussion as well.

The models to predict species richness are not well performing. They all have a weak (0.20 – 0.39) or very weak (< 0.20) R^2 -value. An explanation for that can be that a spectral signature is a representation of the functional characteristics more than the species characteristics, so that accordingly functional diversity will be evaluated rather than species diversity (Tilman, 2001). Certain functional traits (e.g. specific leaf area, leaf nitrogen content...) can be measured in situ to compare if spectral models are better in predicting those traits than the species itself. By performing flights during different seasons, tree phenology can also be taken into account which can improve the models to predict species richness (Madonsela et al., 2021). It looks like longwave infrared radiation is not useful to predict species richness since it results in images with the same mean and standard deviation for each plot. However, it should be noted that the resolution of this band is lower, which makes the variable less reliable than the others.

Including a vertical dimension, i.e. plant height data, significantly increases the model performance. This confirms the results of other studies (Gini et al., 2018; Peng et al., 2021). The positive effect size indicates that the higher the variation in plant height, the higher the species richness. The variation in vertical tree structure both in even-aged and uneven-aged stands is therefore a good indicator of local biodiversity (Peng et al., 2021). For that reason, it is important to always include a vertical component in models to predict species diversity and maybe this is even more required than spectral data. The R^2 -values of the combined model with spectral data and the plant height model without spectral data to predict species richness do not differ much. Moreover, in the combined model, the standard deviation of the plant height was the only significant variable, confirming its importance.

Improving the accuracy of the plant height measurements will probably also improve the model quality. This can be done in different ways. First, collecting digital surface model LiDAR data with cm spatial resolution would give a very accurate representation of the tree structures but these sensors are very costly. Another possibility is to execute double grid flight missions instead of single grid missions. This results in a more accurate point cloud image from which plant height can be extracted but the flight and processing time will increase which is not always a better option because of reasons that will be explained in section 4.4. A third way to improve plant height data is flying during two different seasons over the same site. During early spring with leaf-off conditions it is possible to generate an accurate digital terrain model, while in summer an accurate digital surface model can be obtained. Combining both will result in a more accurate canopy height model (Nasiri et al., 2021).

4.2 Tree Productivity can be Predicted by Spectral Data

UAS-based tree height data was used as proxy for productivity in this study. The model to predict tree productivity based on spectral data has a strong accuracy (R^2 -value = 0.72). Productivity can be accurately predicted by functional traits (Van de Peer et al., 2018). Since spectral data is related to functional characteristics, it makes sense that productivity can be predicted based on spectral data. In the developed model, the NDVI has a significant large positive effect on the plant height. A possible explanation is that the NDVI is inversely correlated with physiological stress and positively correlated with photosynthetic activity (Dash et al., 2018; Wang et al., 2004). Therefore, an increased NDVI generally relates to higher productivity. According to the model, a higher red edge band value correlates to a decreased plant height. This could be explained by the relation between red edge reflectance and tree stress (Masaitis et al., 2013). Stressed trees will be less productive compared to healthy trees. Some studies also indicate that red edge reflectance is related to the leaf area index, which in turn is correlated with tree productivity (Arias et al., 2007; C. Wang, 2021).

4.3 UAS-based Plant Height Data Confirms the Biodiversity-Productivity Hypothesis

The model to predict tree productivity based on species richness confirms the biodiversity-productivity hypothesis: higher species richness results in higher productivity. On contrary, the net diversity effect, which compares the observed yield

with the expected yield, shows no significant increase with increasing species richness at each FORBIO site. However, in 80% of the mixed plots a positive net diversity effect is observed proving overyielding in polycultures. The study performed by Van de Peer et al. (2018) at the FORBIO sites in Zedelgem and Gedinne six years after planting showed similar results: a positive net diversity effect in 83% of the mixed plots. Their results were based on in situ tree diameter and height measurements.

At the Hechtel-Eksel and Gedinne FORBIO sites, the observed net diversity effect in monocultures is not significantly higher than in polycultures. Compared to Zedelgem, where the plots with more than two species have a significant higher net diversity effect, the site in Hechtel-Eksel was established two years later. This could be an explanation why no significant overyielding as in Zedelgem is present yet. It takes several years before species can benefit from complementarity, which leads to higher productivity. However, in high-density plantations, the higher productivity in mixtures compared to monocultures could already be visible after a few years (< five years; Cardinale et al., 2007). Another reason for the observed non-significant net diversity effect could be the poorer sandy soil present in Hechtel-Eksel, compared to a richer loamy soil in Zedelgem. The accuracy of the UAS-based plant height measurements as predictor for tree productivity could also be a possible explanation. However, this accuracy issue could be solved by improving the plant height model generation as discussed in previous section.

The two FORBIO sites in Zedelgem and Gedinne are established in the same year. However, in Gedinne there is no significant higher net diversity effect in mixed-species plots. The variability in net diversity effect is also larger in Gedinne than at the other two sites. The reason for that could be that the Gedinne FORBIO experiment consists of two subsites with some minor differences in soil conditions. The climatic conditions in Gedinne are harsher compared to Zedelgem. Therefore, fast-growing species that are well adapted to these harsh environmental conditions in Gedinne (e.g. Douglas fir, Japanese larch) have a competitive advantage over other species (Van de Peer et al., 2018). The competitive dominance of certain species reducing the performance of others at the Gedinne site can be an explanation for the lower, non-significant net diversity effect.

In Zedelgem, the mild climate and the high post-agricultural nutrient availability caused the tree species to grow effortless and the species benefited from facilitation rather

than being held back by dominance resulting in higher productivity in mixtures (Van de Peer et al., 2018). These differences point out the context-dependency of the biodiversity-productivity relationship. In Zedelgem, higher levels of species richness did not significantly increase the net diversity effect, similarly as observed in the study of Van de Peer et al. (Van de Peer et al., 2018).

4.4 Further Improving Drone Data Collection

For biodiversity studies, drones have numerous advantages compared to other remote sensing platforms and costly, labour-intensive field surveys. However, this study made it clear that collecting drone data goes hand in hand with a lot of uncertainty as well. First, flight restriction geo-zones pose a limitation on where you can fly. This limits the area where and when you can do research. In case of helicopter training areas, it is announced only one day in advance if they become active. This requires a good relationship with the stakeholders, such as the landowners, as they need to be flexible in giving permission with the date and time of flight missions changing more than once. Collecting data around solar noon will give the best results because less shadow is present in the canopy, but matching this benefit with flight restricted time frames can be challenging.

The weather is undoubtedly a limiting factor in UAS-based studies. In case of rain, even a limited amount, your flights need to be postponed. In countries like Belgium, the weather is often very unpredictable, which again makes flight planning difficult. Also, when the weather changes during the flight mission, the mission needs to be aborted and may be repeated later or on another day, which makes the variability between different flight missions at the same location larger. Small gusts of wind can suddenly rise, which significantly decrease the accuracy of the multispectral data. For example, during the last flight missions in Gedinne, the wind gradually came up – staying within acceptable ranges – which is probably the cause of some unprocessed parts during the MAPEO pre-processing. The DLS 2 sensor, which allows flying under non-constant light conditions, is a big improvement in creating less uncertainty. This widens the options for possible flight executions.

It is better to make the flight mission plans in advance, based on the exact perimeter of the region of interest, than doing this in the field such as done during this study. This will ensure an exact overlap with the field data during processing. For example, in

Hechtel-Eksel, one flight mission plan was drawn incorrectly whereby two plots needed to be excluded for further analysis. In this case, it was still quite easy to distinguish the experiment from the surrounding vegetation on an aerial map, but when the vegetation grows, this will become harder and thus more important to make the flight mission plans beforehand. However, it is still very important to doublecheck everything in the field because small adaptations to the flight mission plans could be required e.g. to avoid interaction with large trees, power lines etc.

Another improvement that can be made, is increasing the side and front overlap from 75% to 85%. The quality checks during the MAPEO pre-processing indicate that for almost every flight mission the real overlap was too low, at some points even lower than 65%. The real overlap appears to be inhomogeneous during the entire flight – despite the fixed distance interval setting – resulting in some pixels with an overlap being lower than the pre-programmed one. This reduces the quality of the images significantly and even creates some data gaps. Studies prove that overlap settings are usually the variable with the largest effect on the processing quality (de Lima et al., 2021; Ottoy et al., 2022).

However, the trade-off between image resolution and computing power needed to process the images always needs to be considered. Increasing the overlap by a few percentages, can in fact increase the computing time in orders of magnitude when generating for example a digital surface model (Torres-Sánchez et al., 2018). When increasing the overlap, the flight altitude can be enlarged as compensation. In that way, the flight time will not be longer than the battery power can provide and the data quantity to be processed will still be within the acceptable range. Some studies have evaluated the effect of different processing parameters for photogrammetry (de Lima et al., 2021; Ottoy et al., 2022; Young et al., 2022). The chosen altitude, overlap, pitch and even the software all influence the result. However, few studies on optimizing the parameters regarding UAS-based forest biodiversity studies have been performed up to now.

Measuring some ground control points in the field will improve the data quality as well. Even though the drone is connected to the RTK network, this will still enlarge the precision. As a result, less size reduction of the plots will be needed during the data processing and therefore more data can be used. Flying over forest ecosystems is harder than over agricultural fields. Therefore, if you just obtained a theoretical pilot

license, I would highly recommend having you assisted by an experienced pilot in more difficult environments such as present in this study to ensure safety.

MAPEO uses WGS84+EGM96 as standard CRS for pre-processing data from DJI multispectral sensors. However, our original input data had another CRS, i.e. WGS84, which caused incorrect, higher values in the digital surface models and digital terrain models. To avoid such problems, this always needs to be checked beforehand. However, our applied correction did not influence the final results because all pixels were treated equally.

5 Conclusion

Collecting UAS data for forest monitoring applications has numerous advantages because of its low cost and high flexibility. However, UAS-based studies have also some disadvantages since they are subjected to uncertainties concerning weather and geo zone flight restrictions. For achieving the best result, a strict pipeline needs to be followed in collecting and processing drone data. Further research is advised to optimize the parameters for UAS-based forest biodiversity studies.

Models predicting tree species richness based on spectral data have low R^2 -values. Adding a structural component significantly improves the model accuracy. Based on spectral diversity, it is hard to predict species diversity, since spectral diversity is rather related to functional diversity. In general, UAS applications have the potential to monitor tree diversity when combined with further research including parameter optimization and assessing season variability for long-term monitoring applications. However, direct monitoring of tree species diversity based on UAS data will always have limitations regarding biodiversity conservation since the ecological importance or rareness of species is not considered.

Spectral data can be used to model tree species productivity with high accuracy. The productivity-diversity hypothesis can also be confirmed based on UAS data. To evaluate its accuracy, plant height data should be collected in situ and compared with the results found in this study. Differences in net diversity effects between the different FORBIO sites indicate the context-dependency of overyielding in mixtures. Therefore, further research assessing the concrete mechanisms causing these differences is required.

7 Appendices

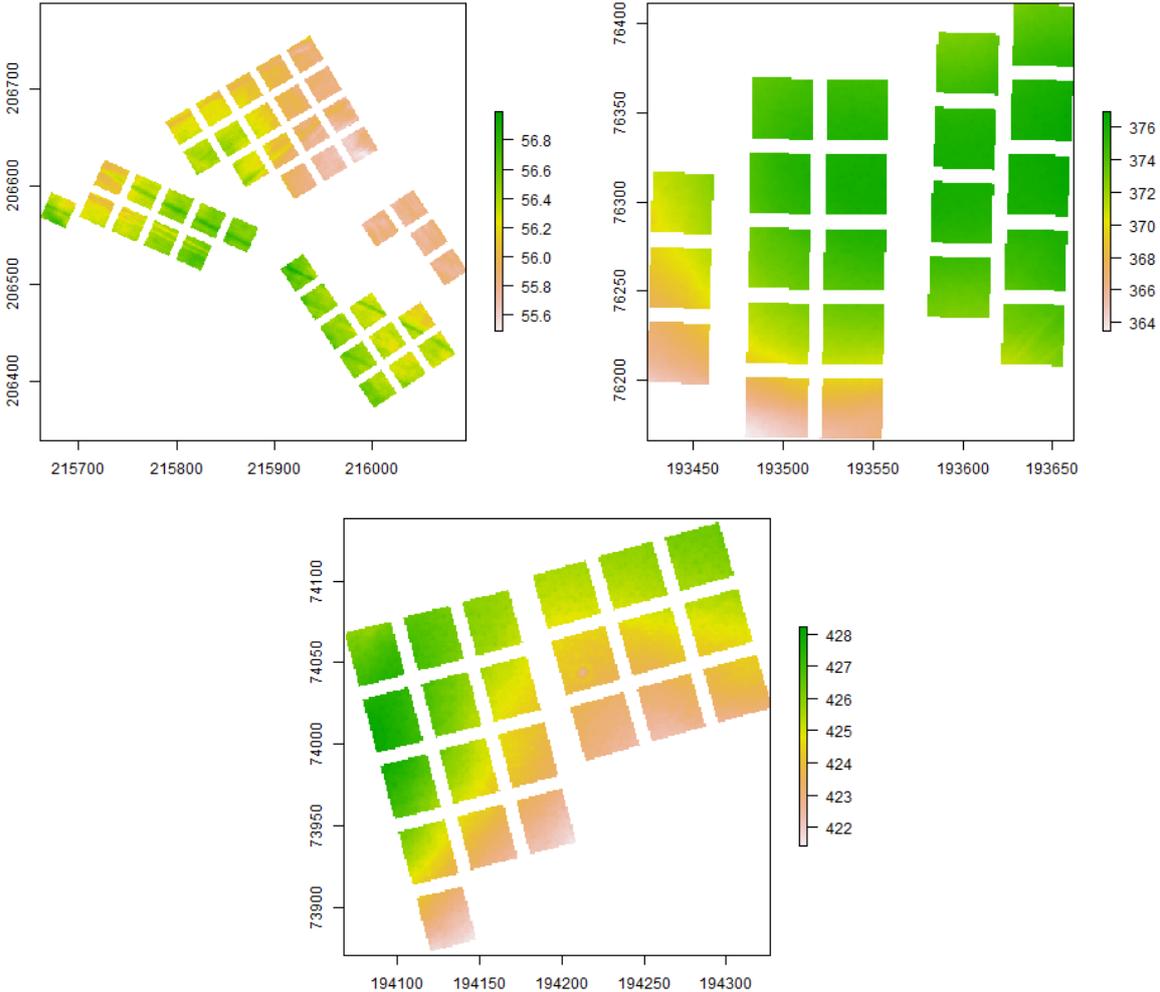

Appendix I List of species present in the FORBIO sites in Belgium.

| Scientific Name | English Name |
|---------------------------------------------|-------------------|
| <i>Betula pendula</i> Roth. | silver birch |
| <i>Larix kaempferi</i> Sarg. | Japanese larch |
| <i>Pinus sylvestris</i> L. | Scots pine |
| <i>Pseudotsuga menziesii</i> (Mirb.) Franco | Douglas fir |
| <i>Quercus petraea</i> (Mattuschka) Liebl. | sessile oak |
| <i>Fagus sylvatica</i> L. | common beech |
| <i>Quercus robur</i> L. | pedunculate oak |
| <i>Tilia cordata</i> Mill. | small-leaved lime |
| <i>Acer pseudoplatanus</i> L. | sycamore maple |
| <i>Larix x eurolepis</i> Henry | hybrid larch |

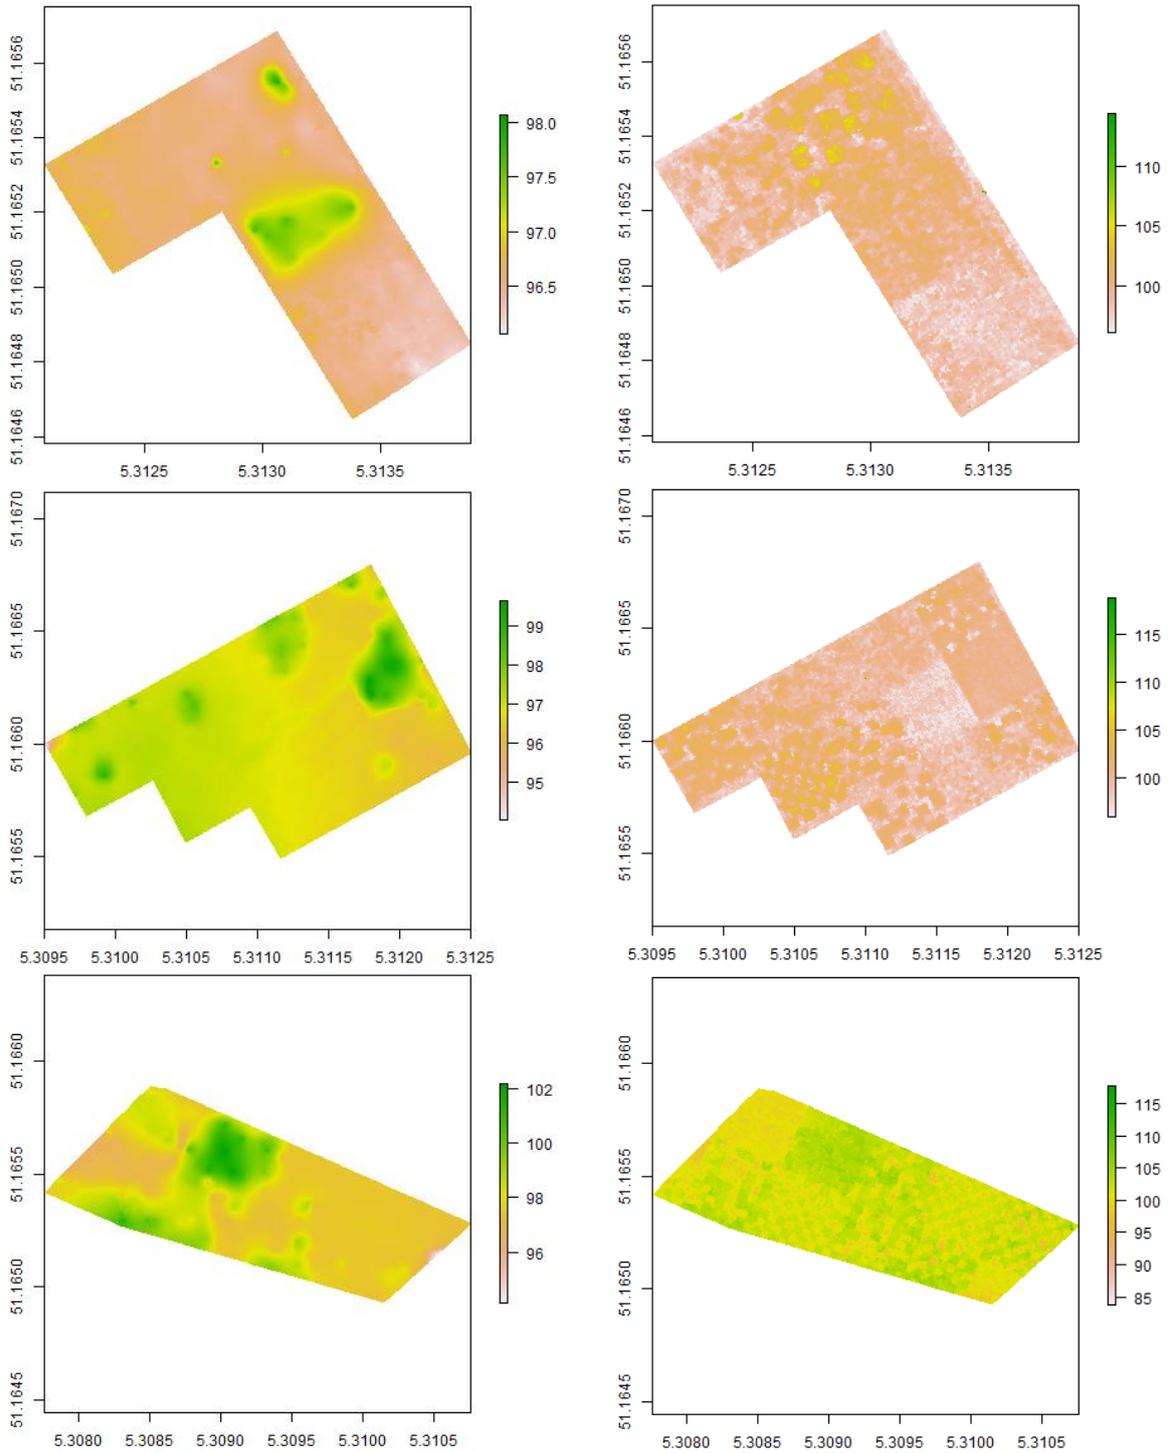

Appendix II Plots of the FORBIO experiment in Hechtel-Eksel (top), Gribelle (middle) and Gouverneurs (bottom) with the colour representing the number of species. On the left the original plot sizes are given and on the right the plot sizes reduced by 4 m at each side

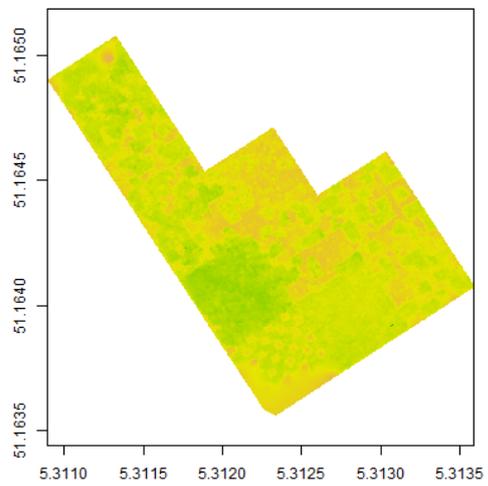

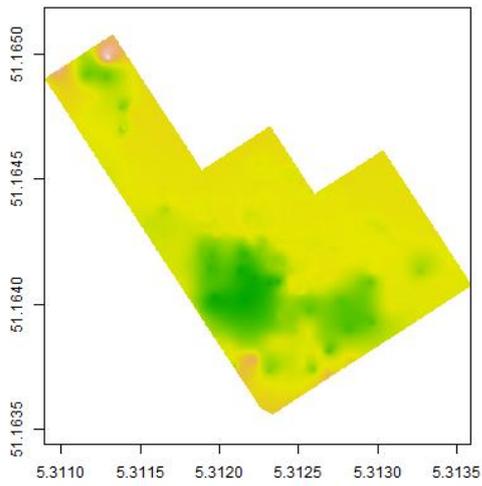

Appendix III Digital Terrain Model in meters of the FORBIO sites is Hechtel-Eksel (top left), Gribelle (top right) and Gouverneus (bottom)

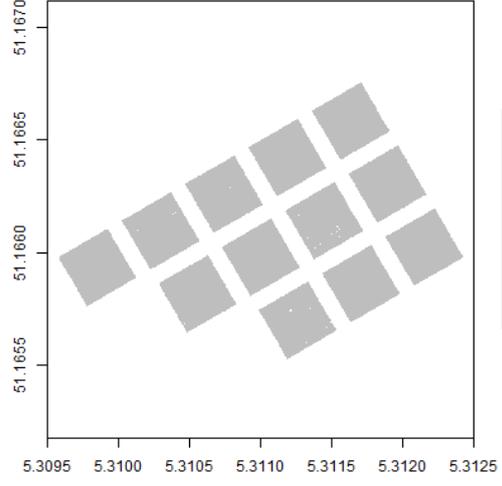

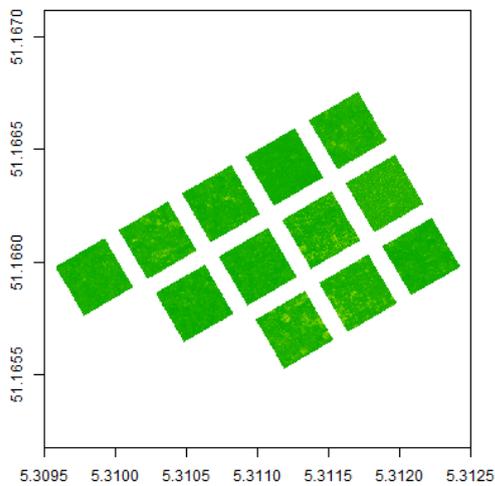

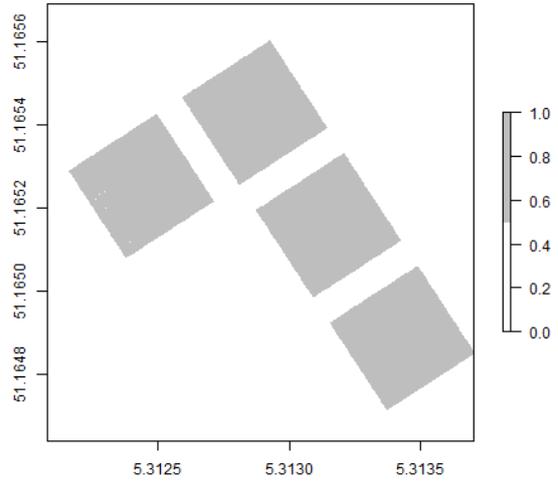

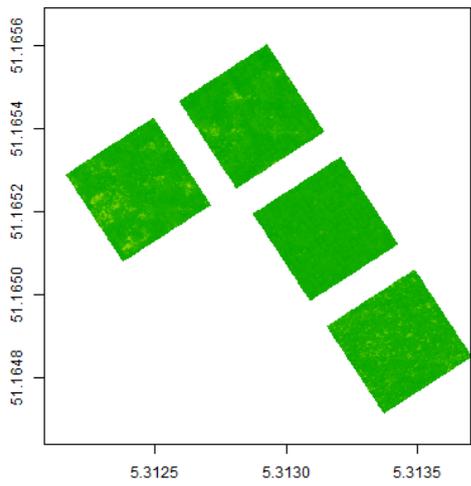

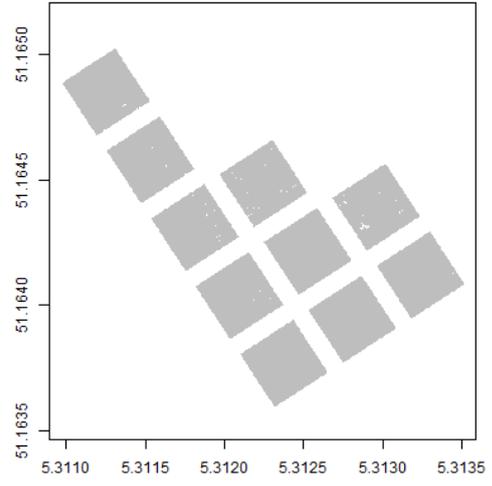

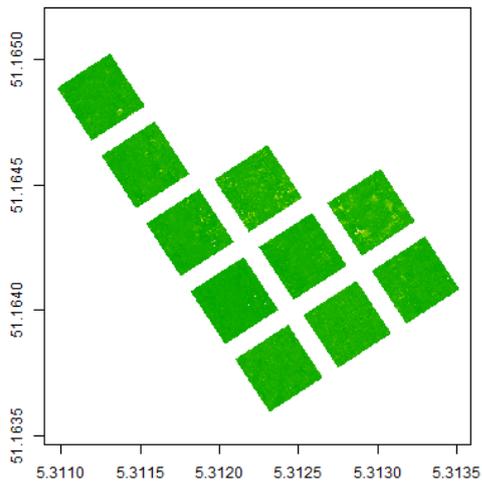

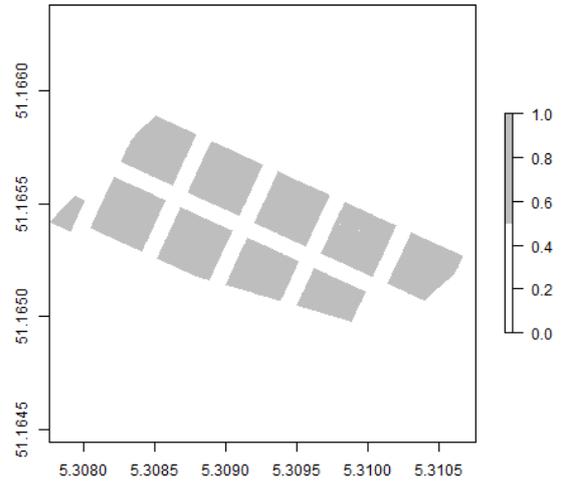

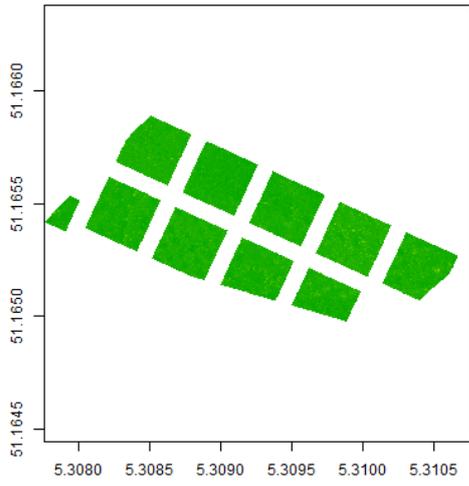

Appendix IV DTM (left) and DSM (right) in meters derived from MAPEO-preprocessed drone data. The results of the four different flight missions over the FORBIO site in Hechtel-Eksel are given (continued next page).

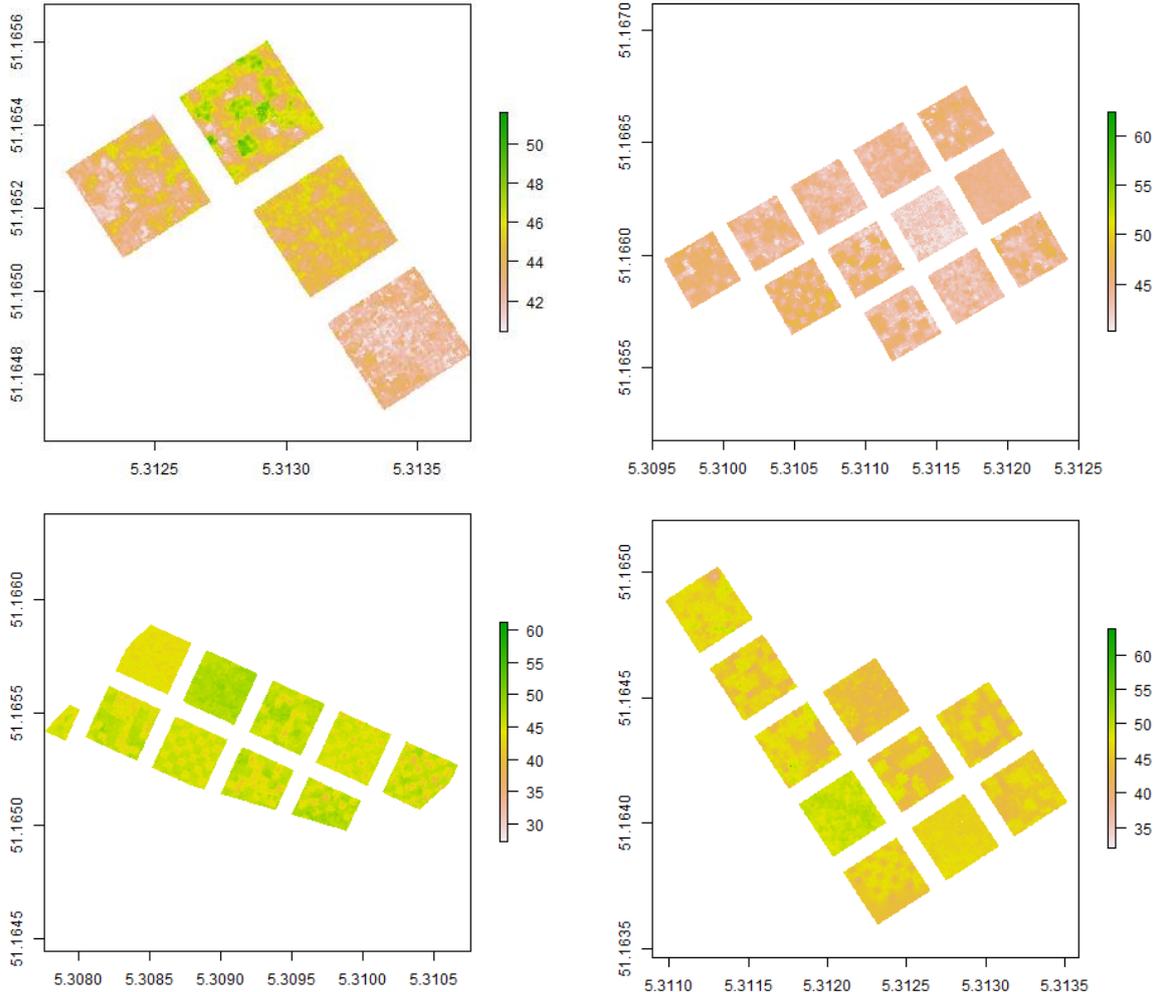

Appendix V Mask layer (right) derived from the NDVI layer (left) where values are lower than 0.3. The results of the four different flight missions over the FORBIO site in Hechtel-Eksel are given (continued next page).

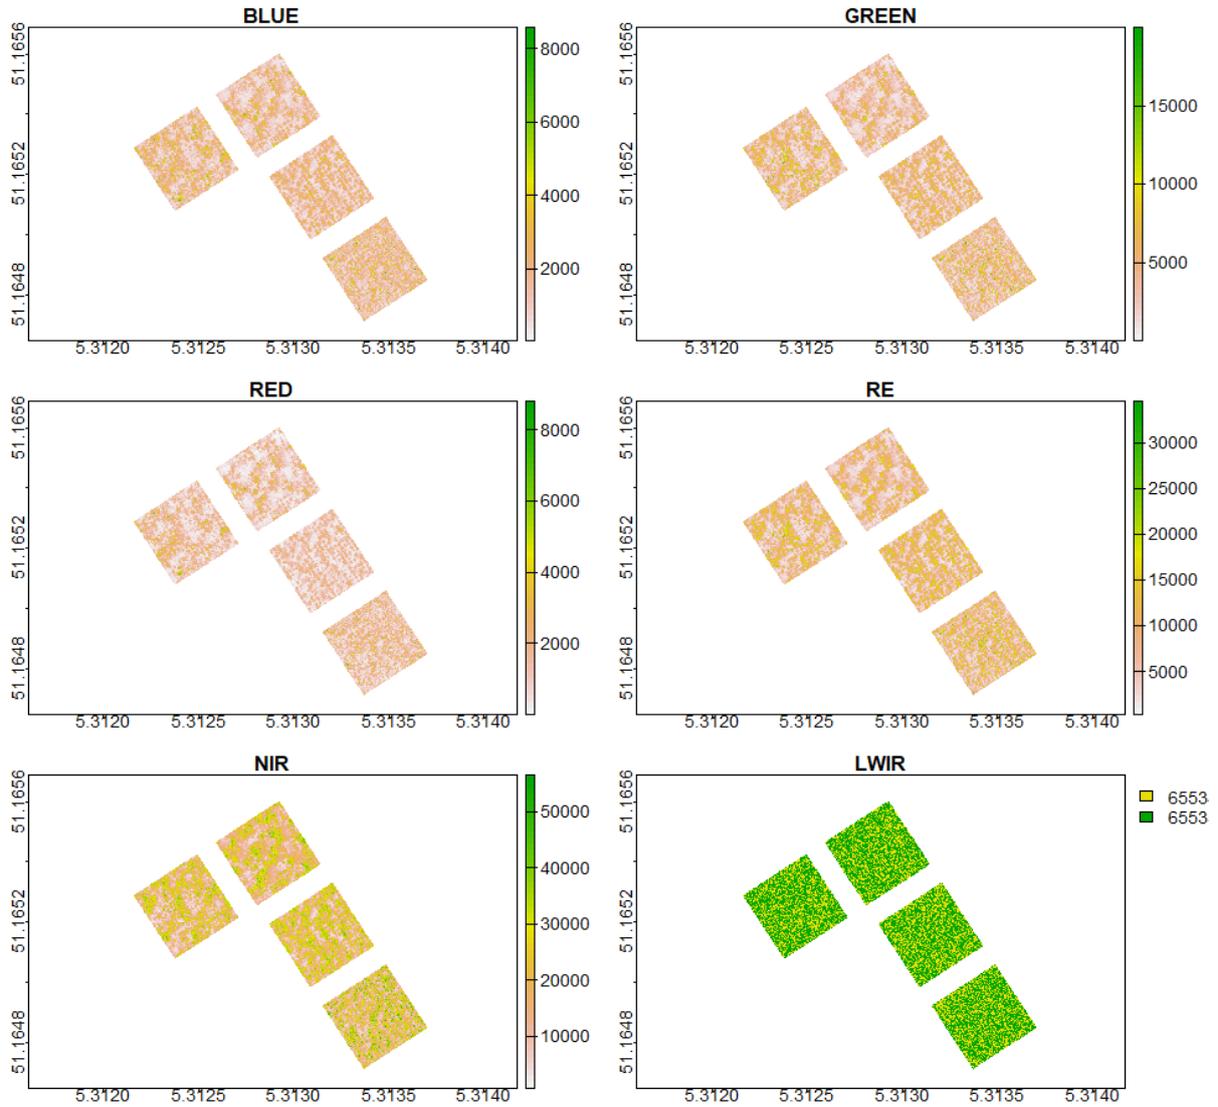

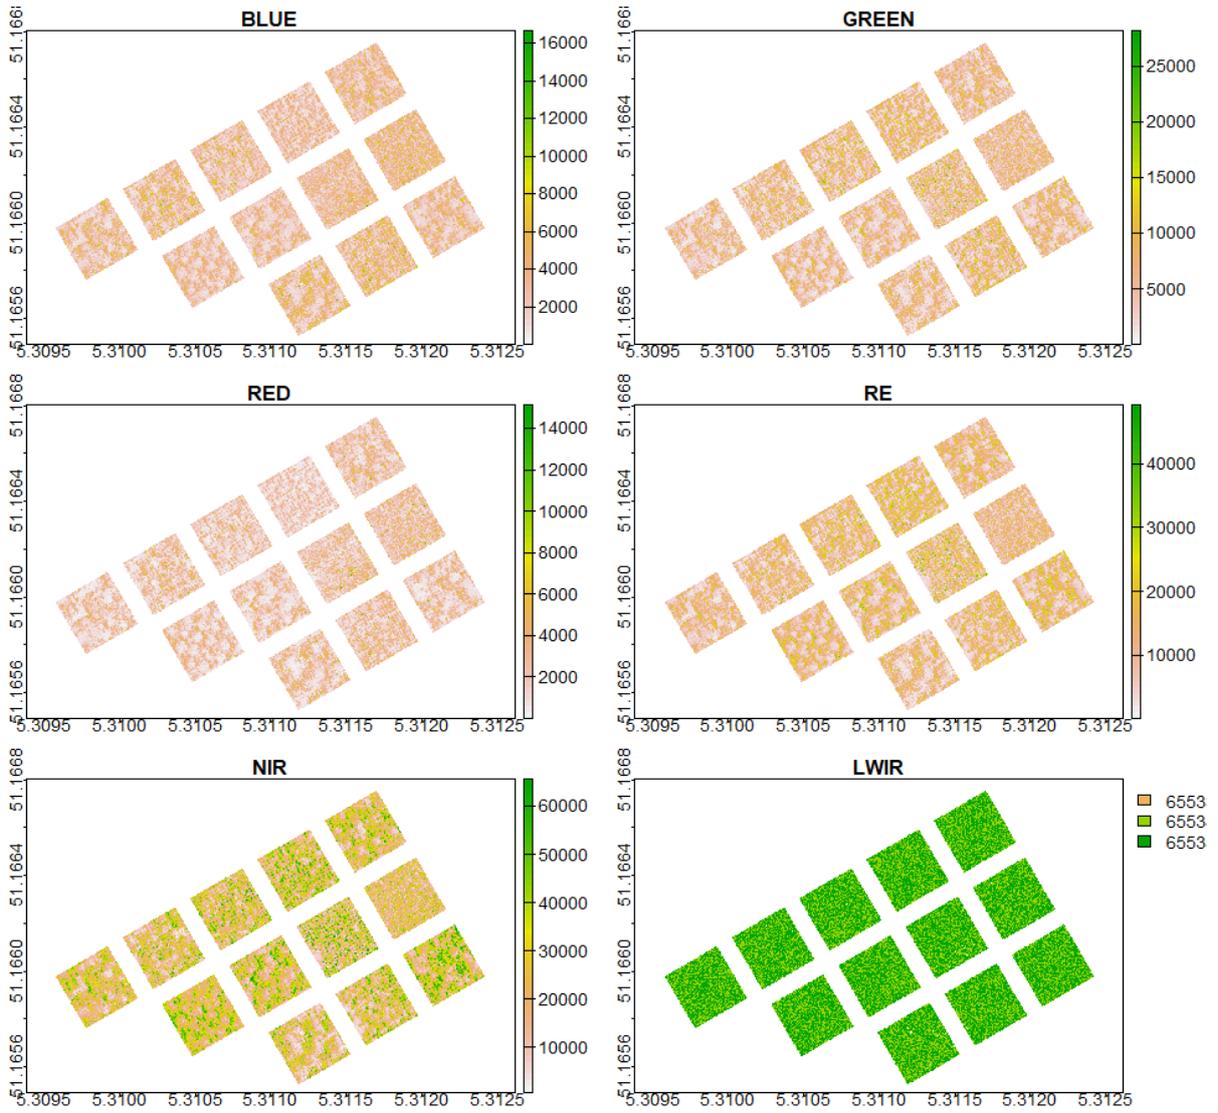

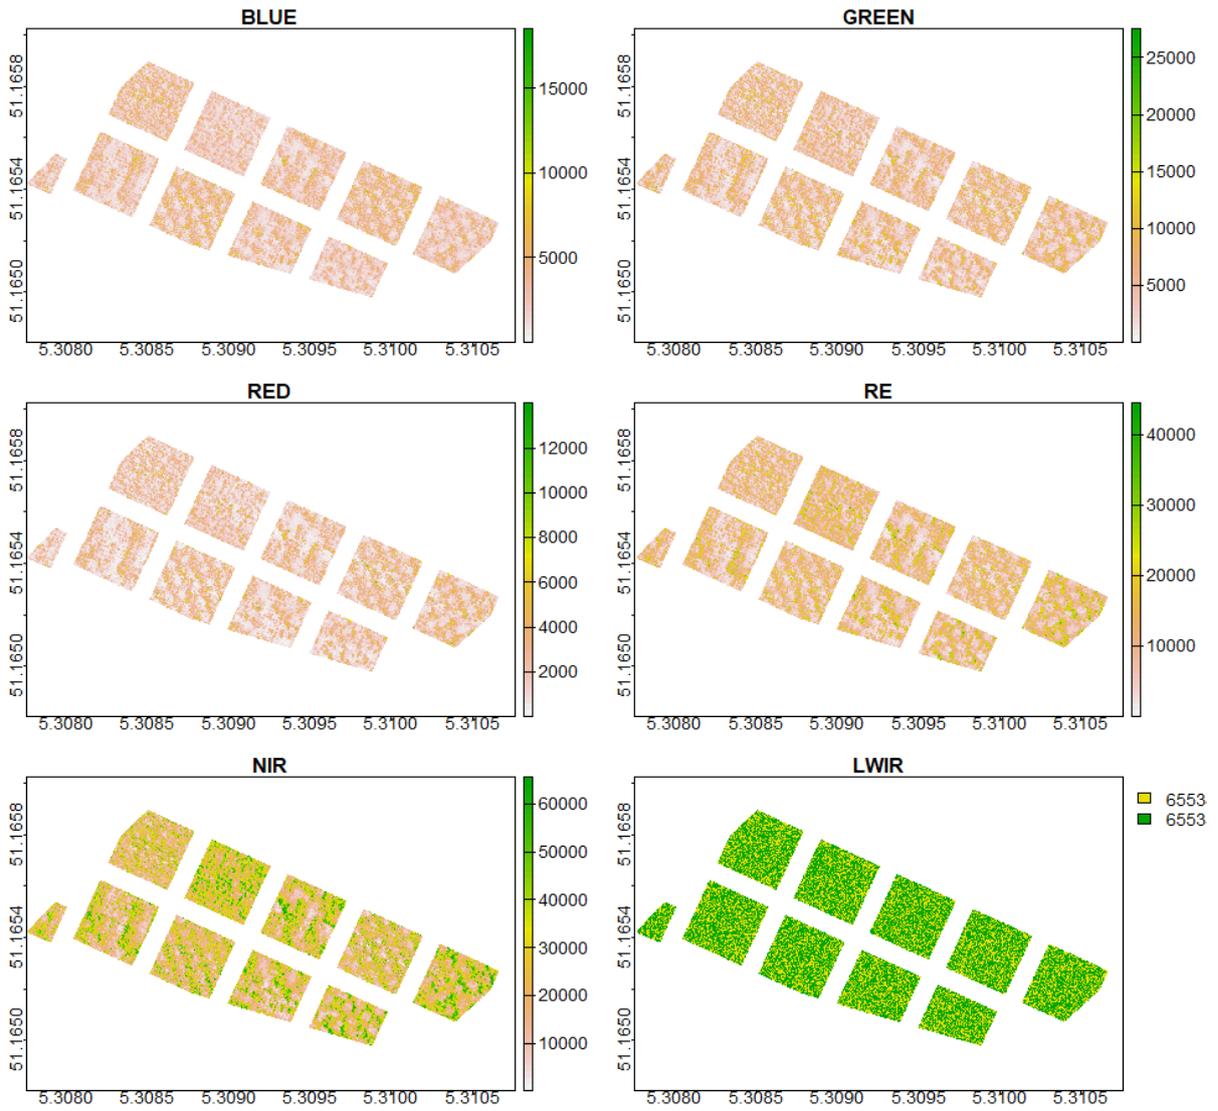

Appendix VI Plant height in meters derived by subtracting the DTM of Flanders from the MAPEO-preprocessed DSM result. The results of the four different flight missions over the FORBIO site in Hechtel-Eksel are given.

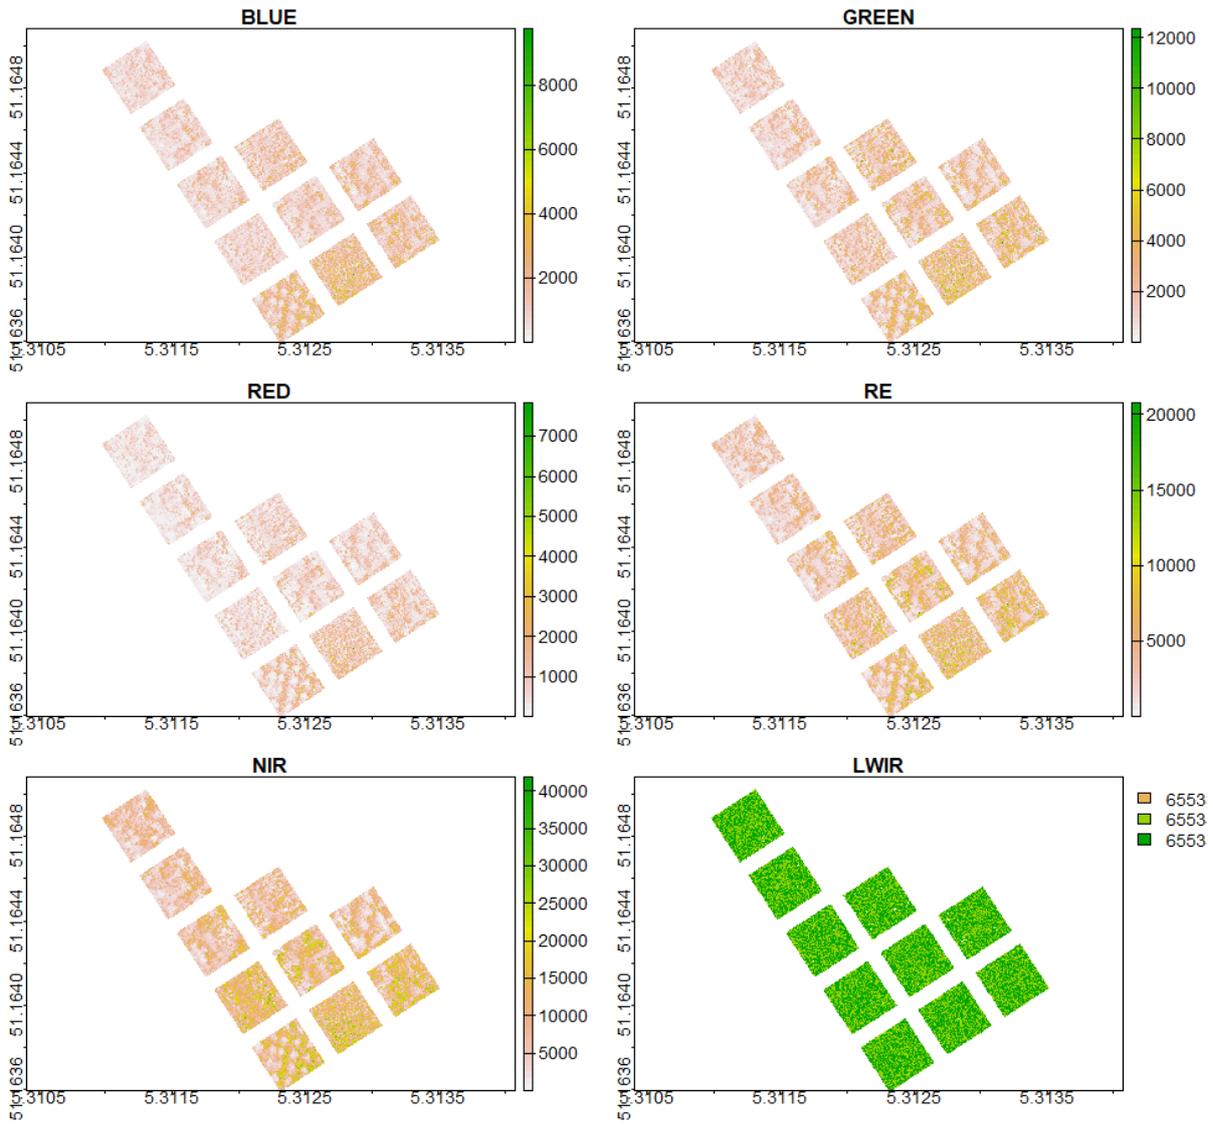

Appendix VII Reflectance drone data after clipping with size-reduced plots of the FORBIO site in Hechtel-Eksel. Six different bands are presented from left to right: blue, green, red, red edge (RE), near-infrared (NIR), longwave infrared (LWIR). The results of the four different flight missions over the FORBIO site in Hechtel-Eksel are given (continued next pages).

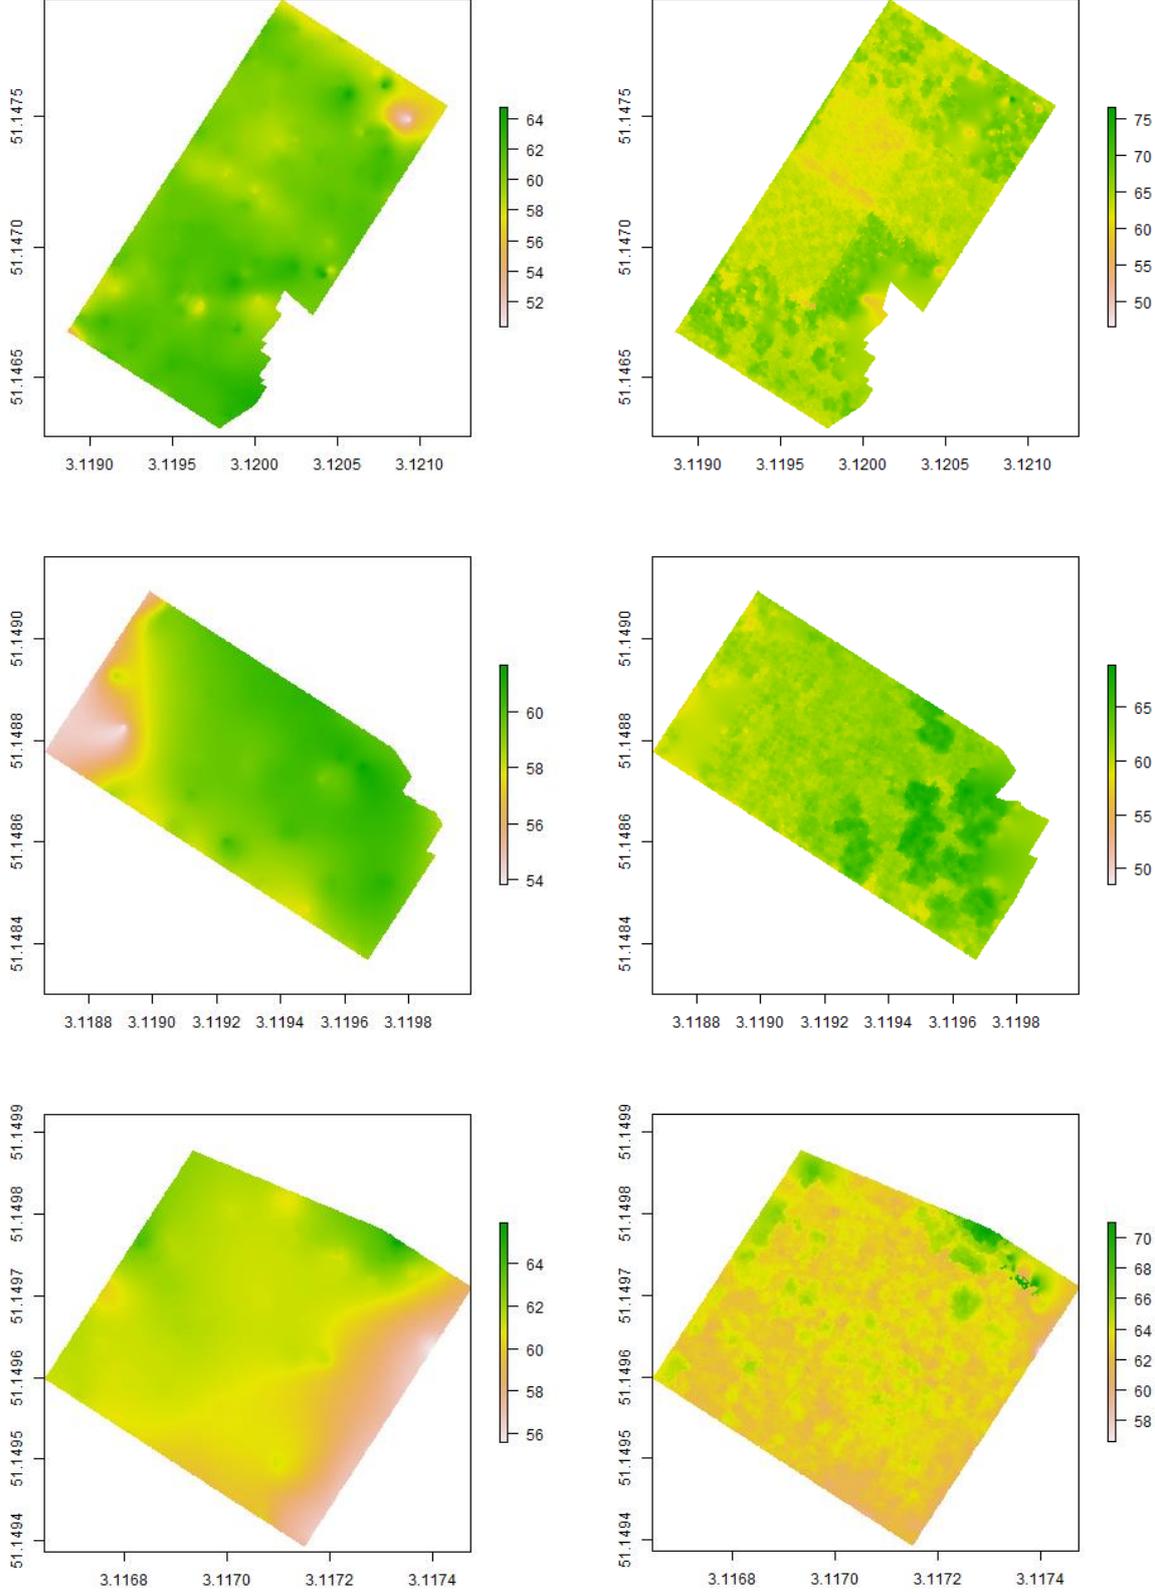

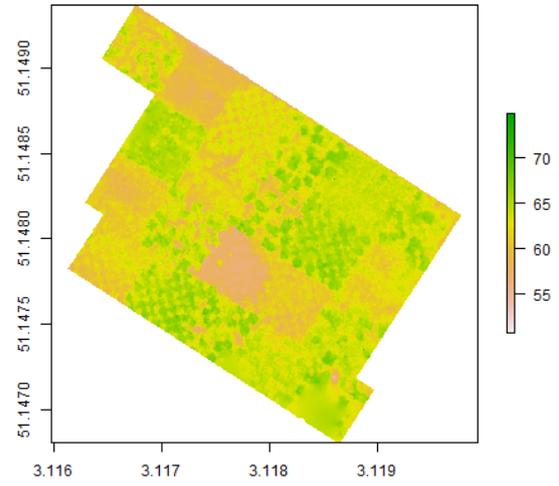

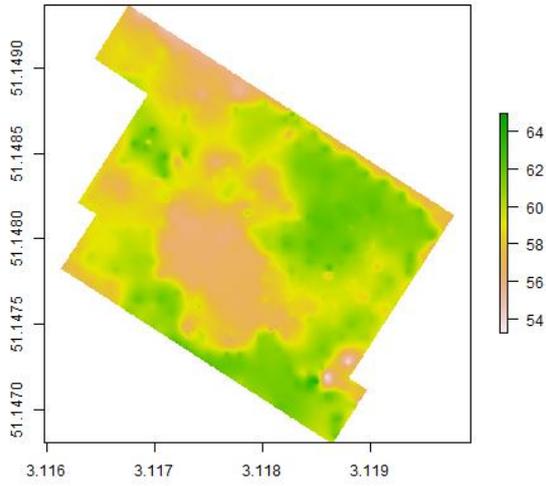

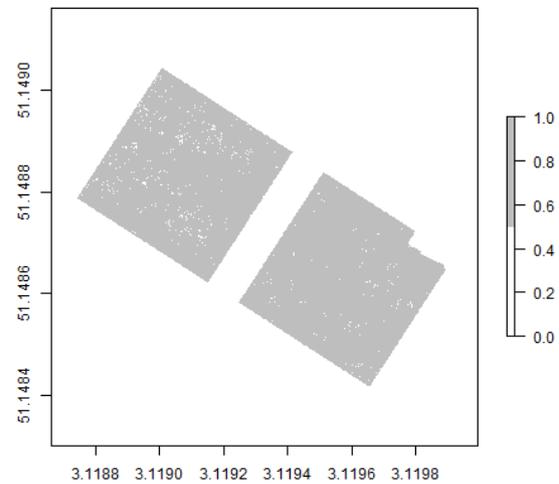

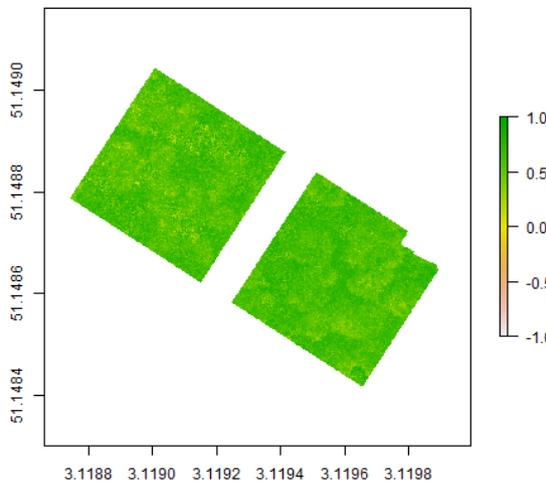

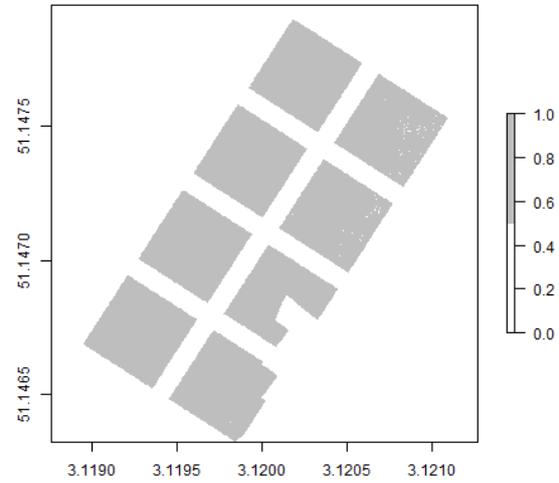

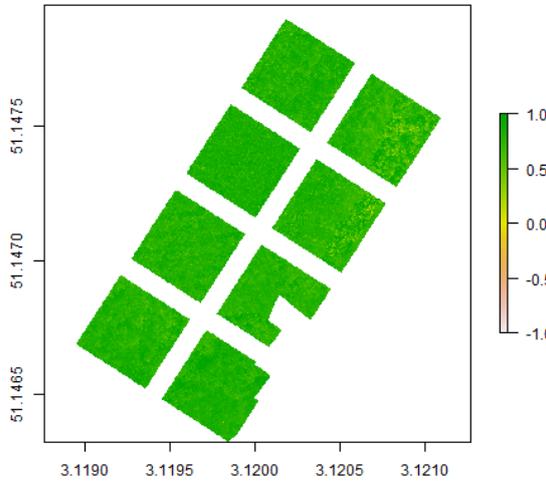

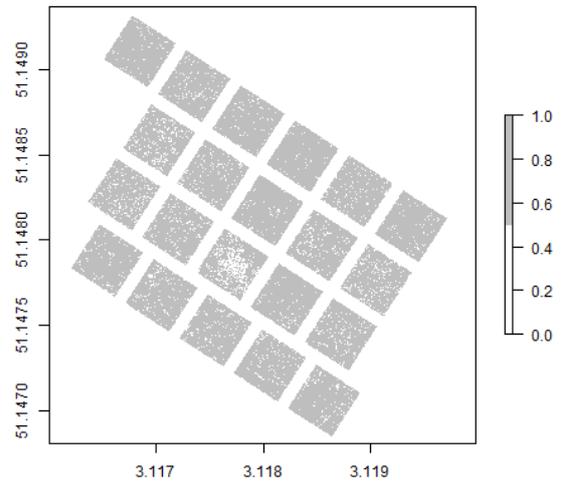

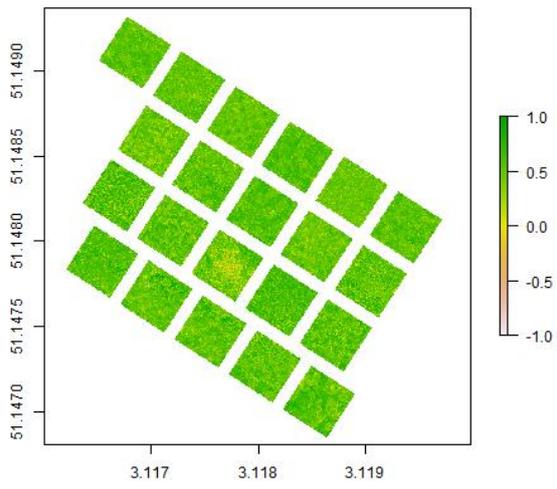

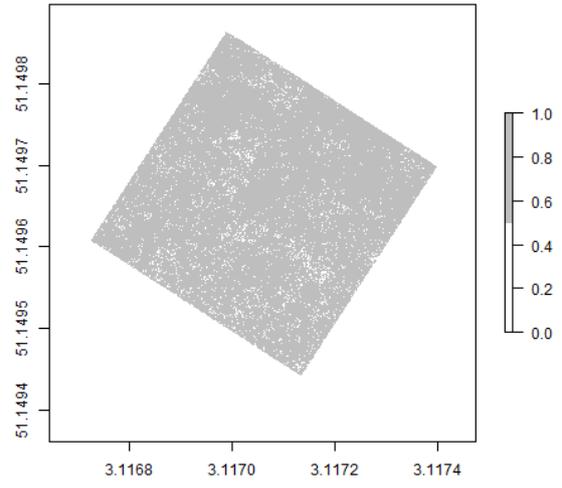

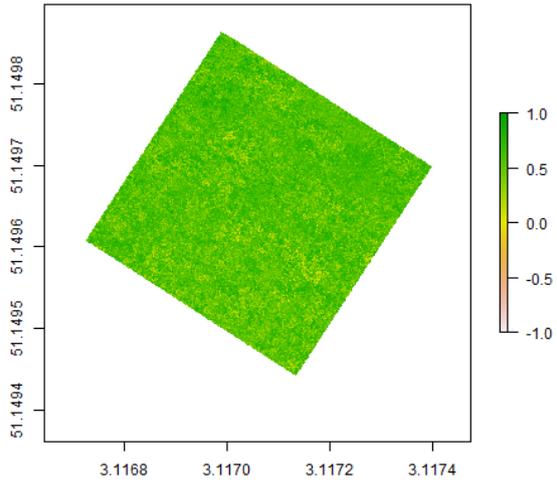

Appendix VIII DTM (left) and DSM (right) in meters derived from MAPEO-preprocessed drone data. The results of four different flight missions, the ones not presented in sections 3.1 and 3.2, over the FORBIO site in Zedelgem are given (continued next page).

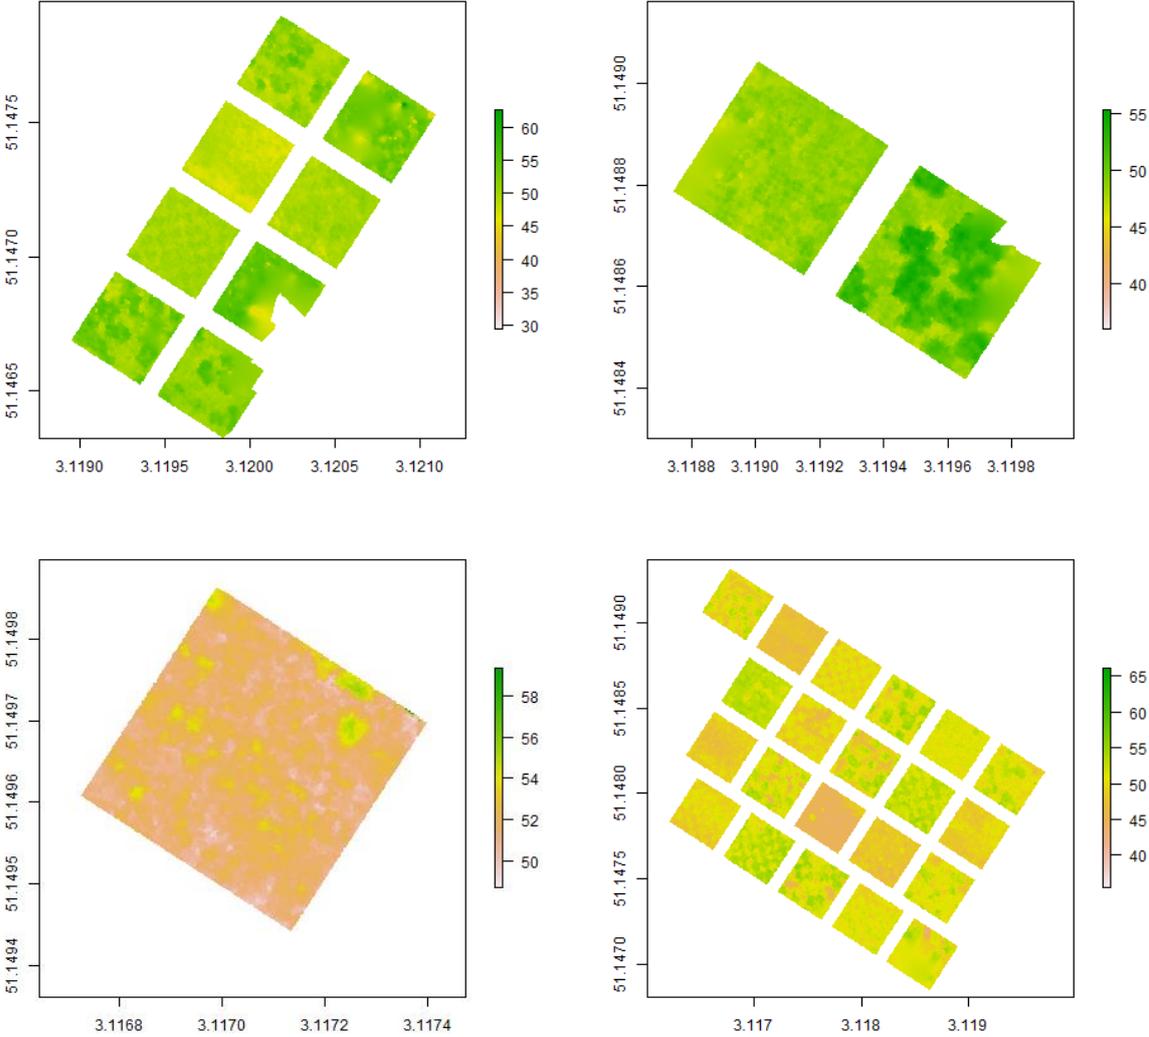

Appendix IX Mask layer (right) derived from the NDVI layer (left) where values are lower than 0.3. The results of four different flight missions, the ones not presented in sections 3.1 and 3.2, over the FORBIO site in Zedelgem are given (continued next page).

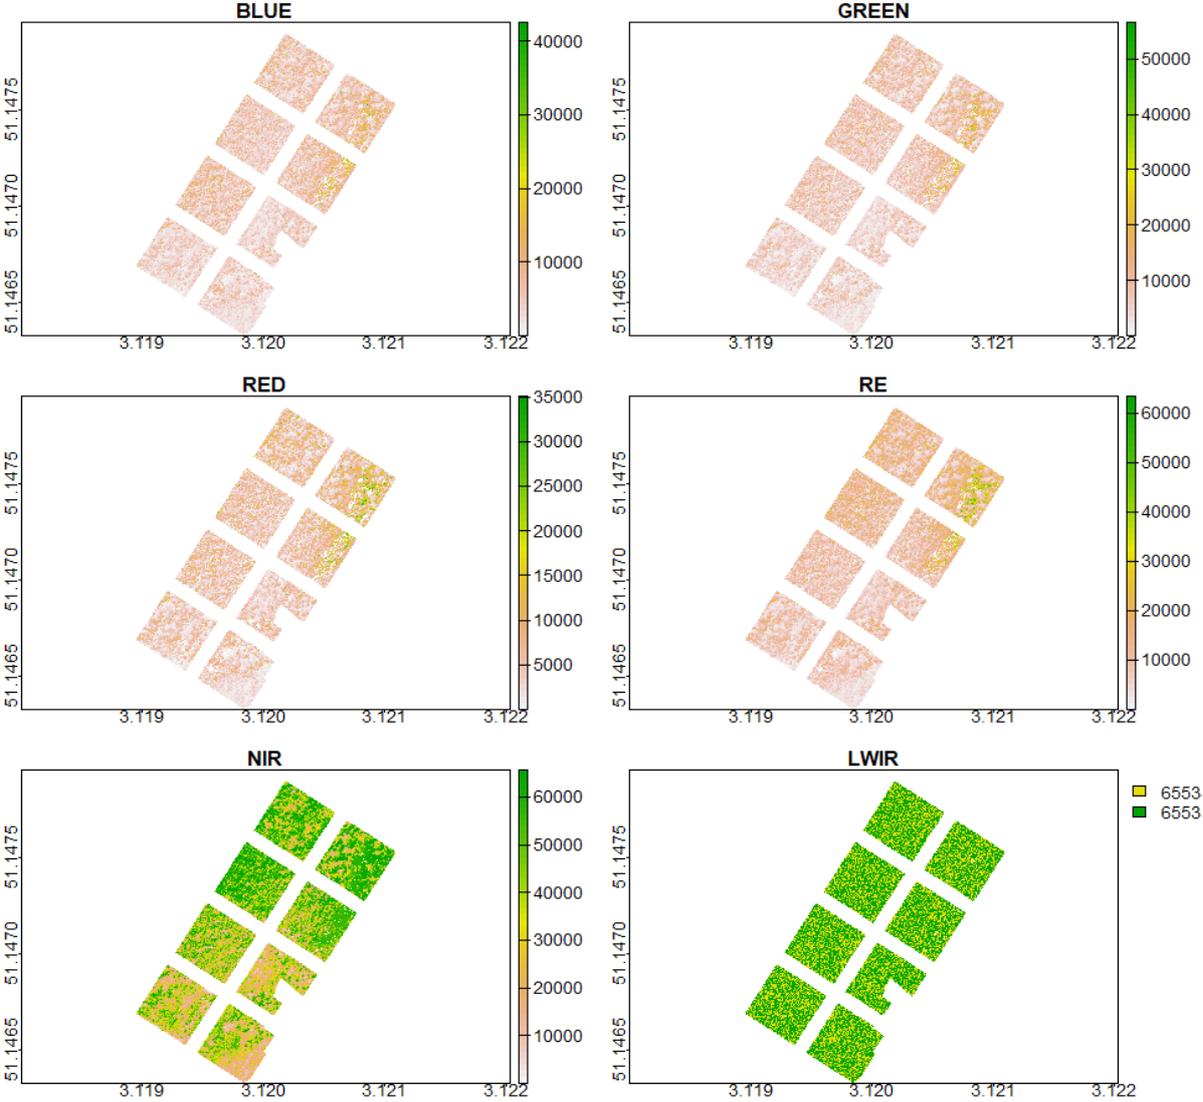

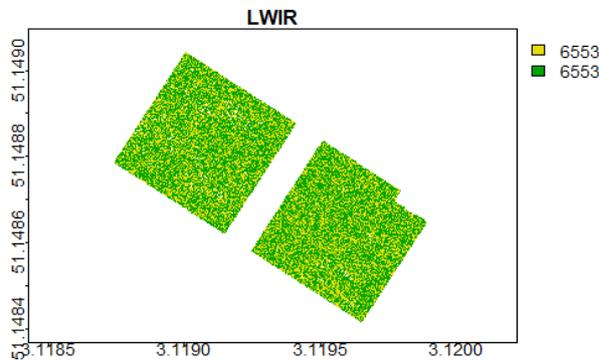

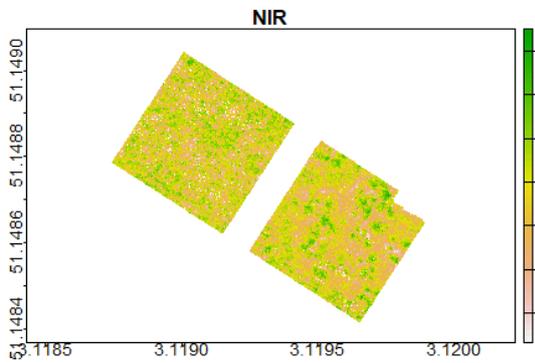

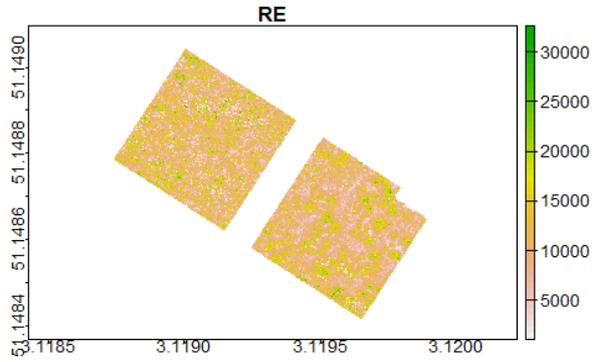

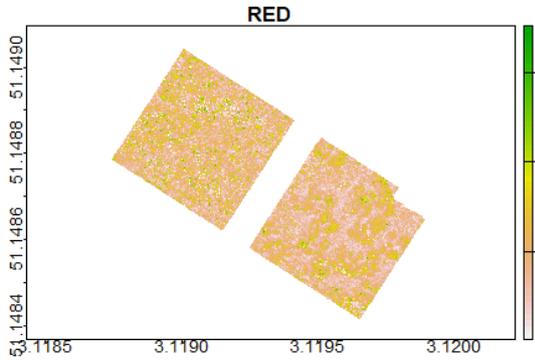

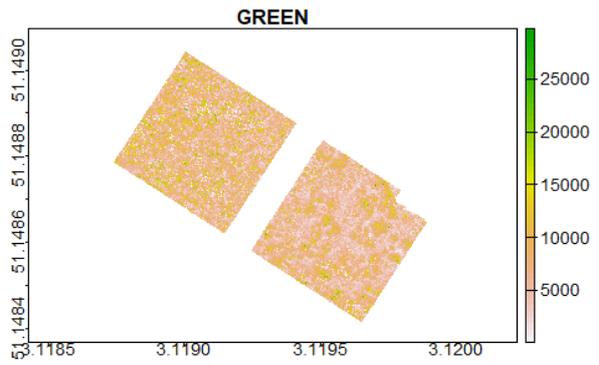

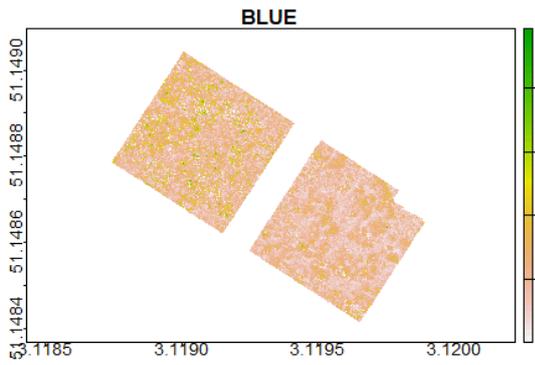

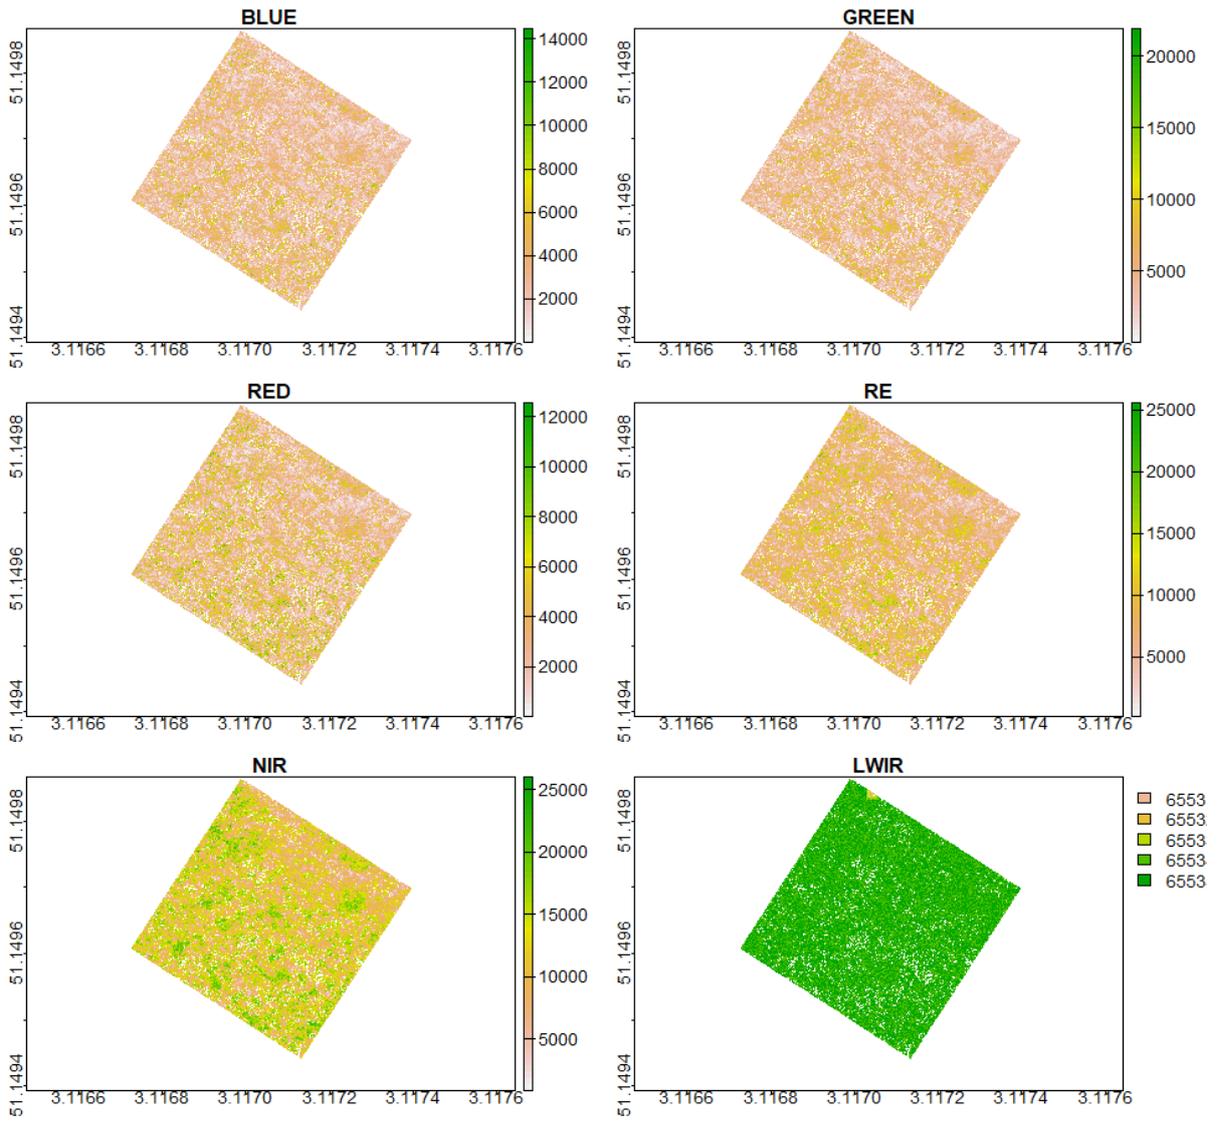

Appendix X Plant height in meters derived by subtracting the DTM of Flanders from the MAPEO-preprocessed DSM result. The results of four different flight missions, the ones not presented in sections 3.1 and 3.2, over the FORBIO site in Zedelgem are given.

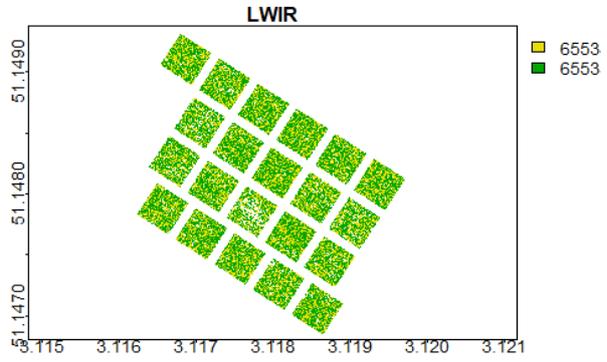

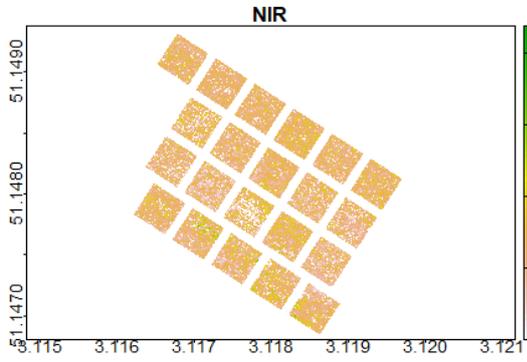

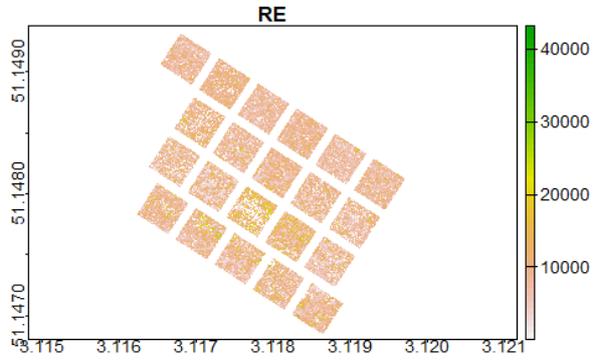

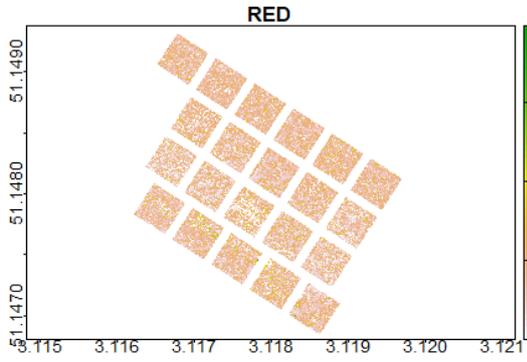

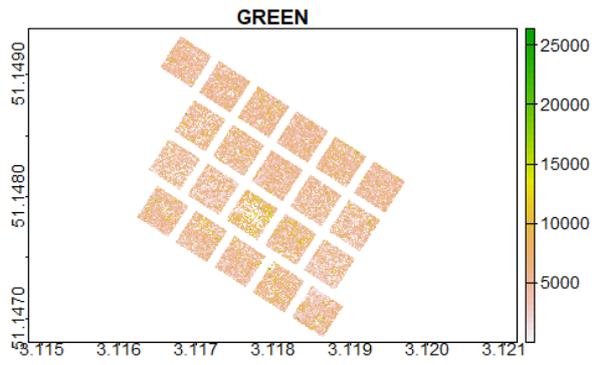

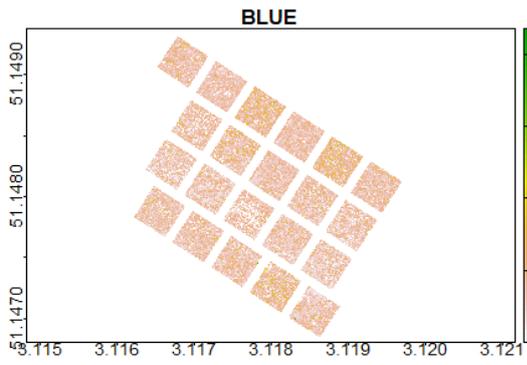

Appendix XI Reflectance drone data after clipping with size-reduced plots of the FORBIO site in Zedelgem. Six different bands are presented from left to right: blue, green, red, red edge (RE), near-infrared (NIR), longwave infrared (LWIR). The results of four different flight missions, the ones not presented in sections 3.1 and 3.2, over the FORBIO site in Zedelgem are given (continued next pages).

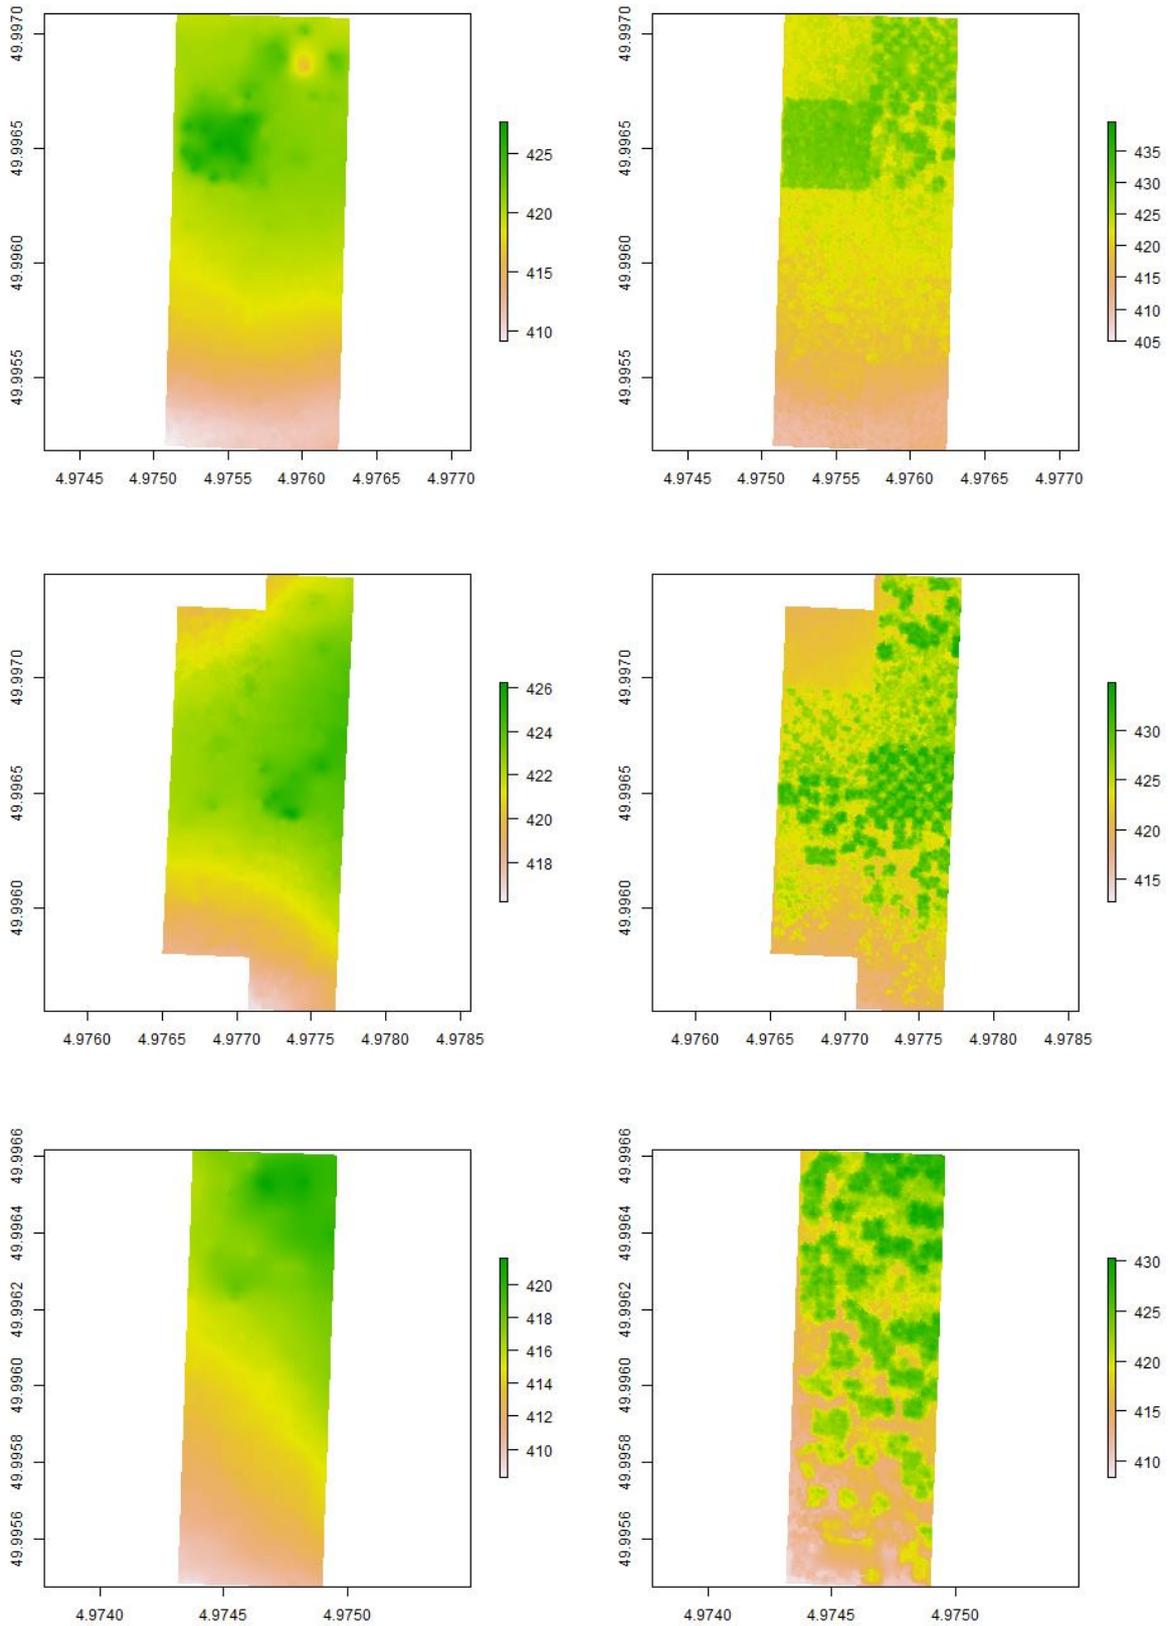

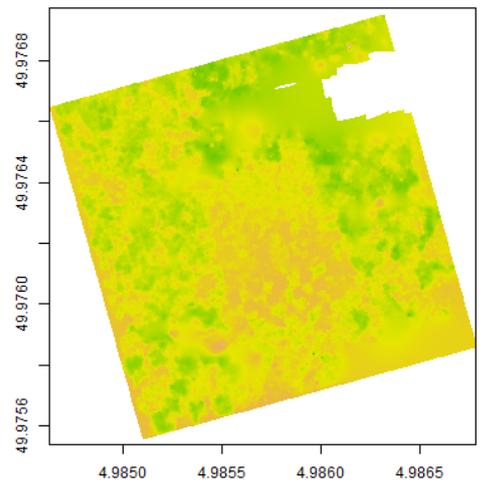

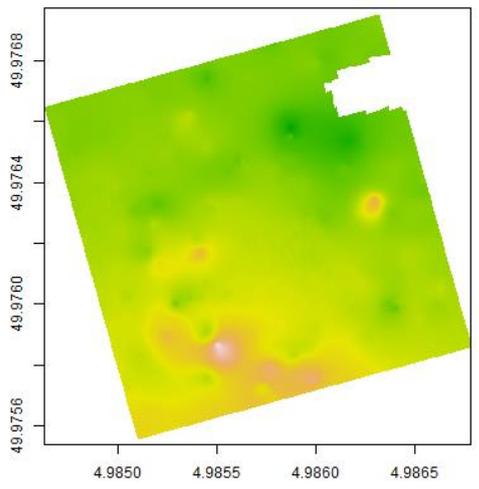

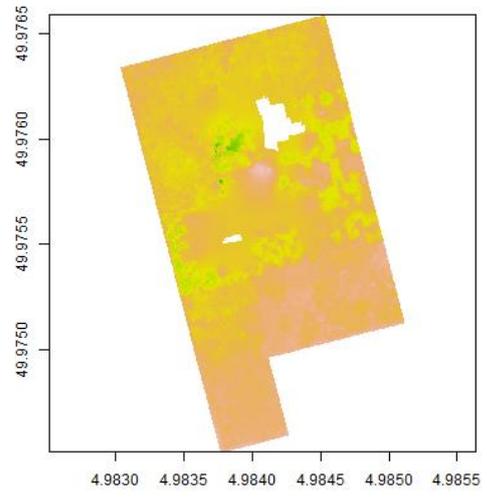

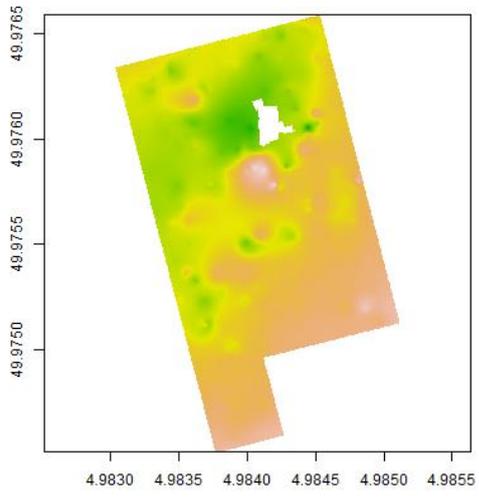

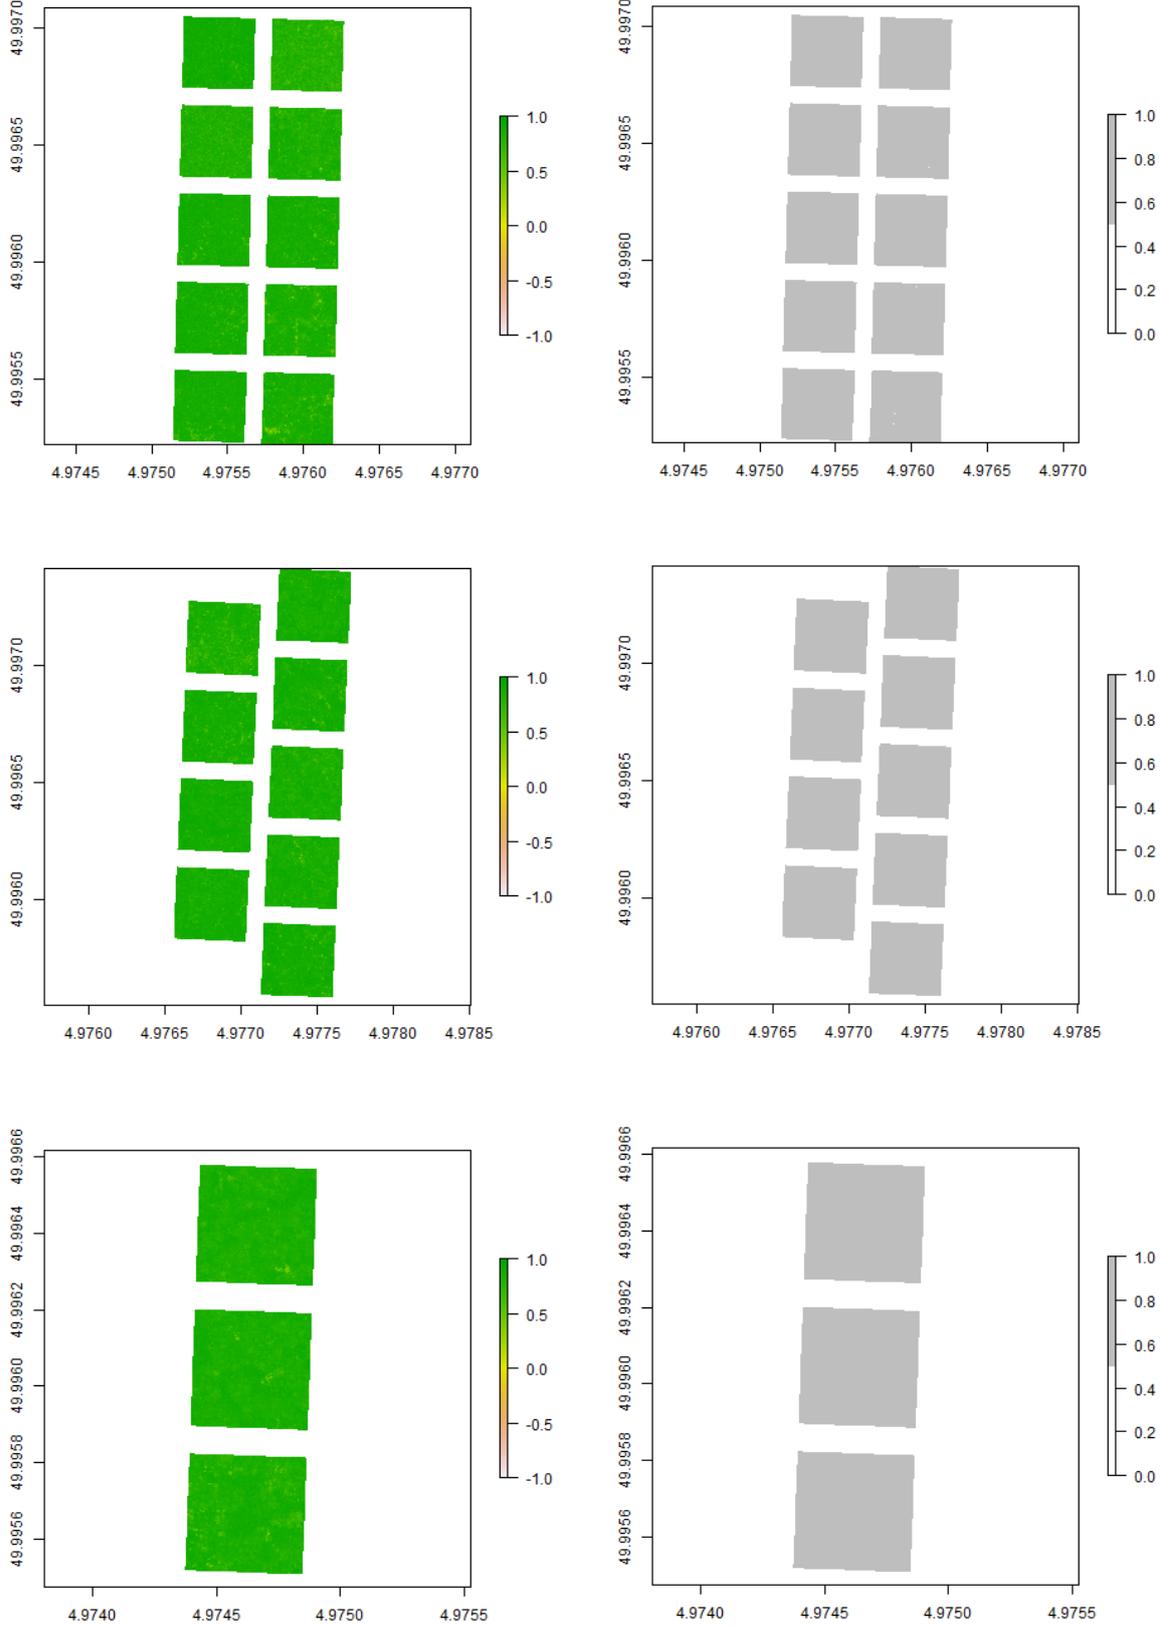

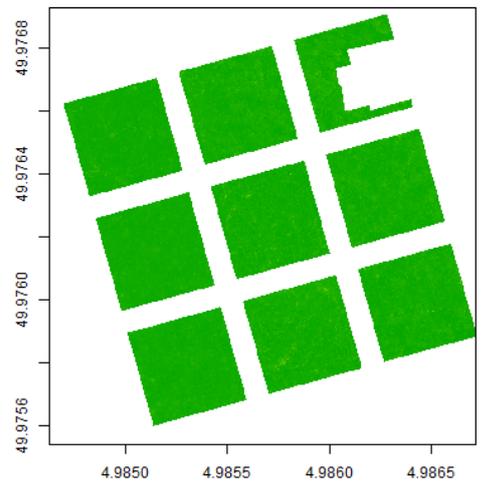

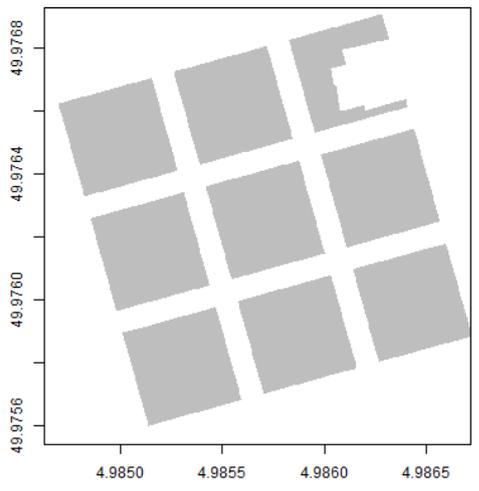

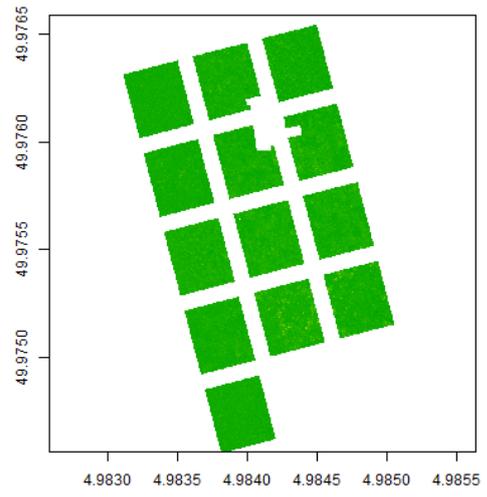

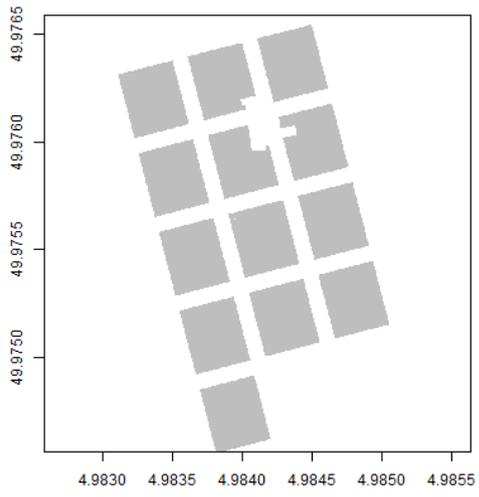

Appendix XII DTM (left) and DSM (right) in meters derived from MAPEO-preprocessed drone data. The results of the five different flight missions over the FORBIO site in Gedine (three in Gribelle and two in Gouverneurs) are given (continued next page).

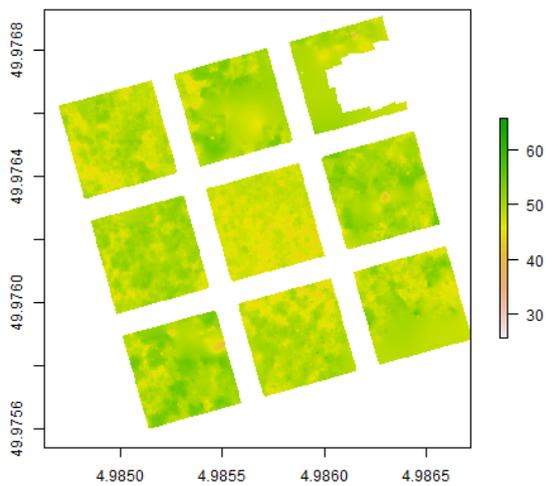

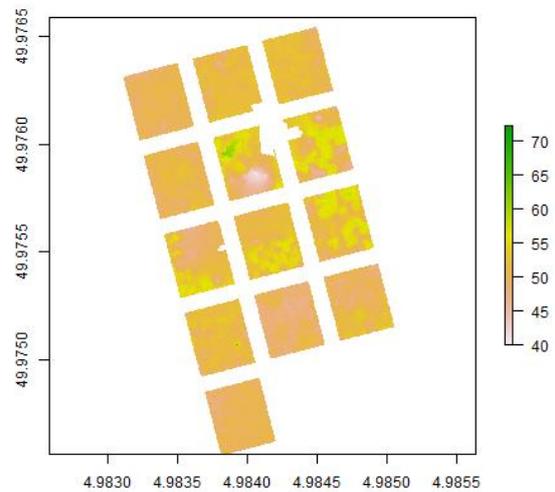

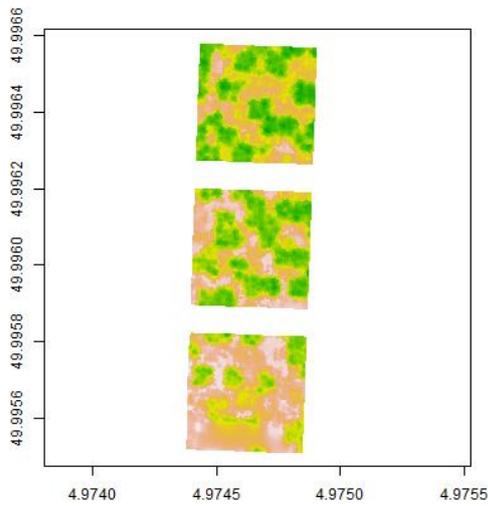

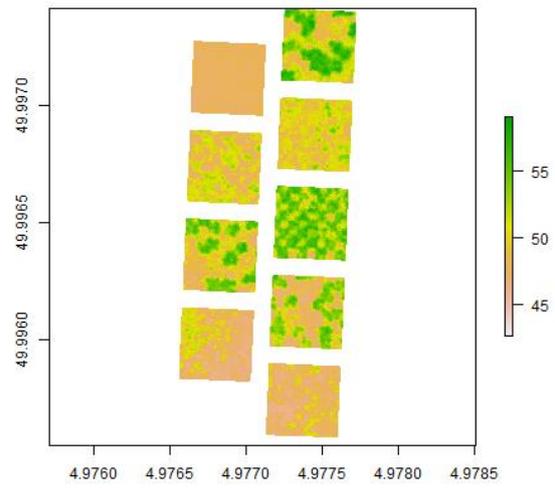

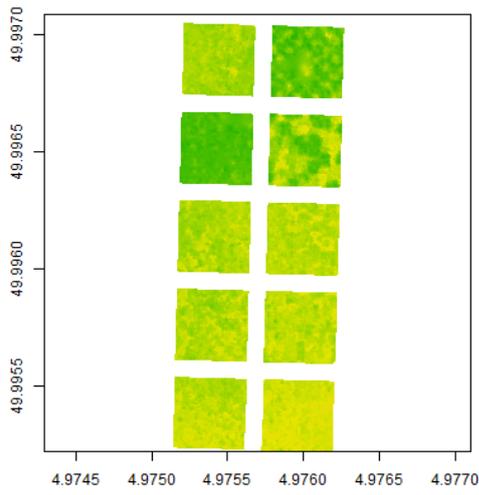

Appendix XIII Mask layer (right) derived from the NDVI layer (left) where values are lower than 0.3. The results of the five different flight missions over the FORBIO site in Gedine (three in Gribelle and two in Gouverneurs) are given (continued next page).

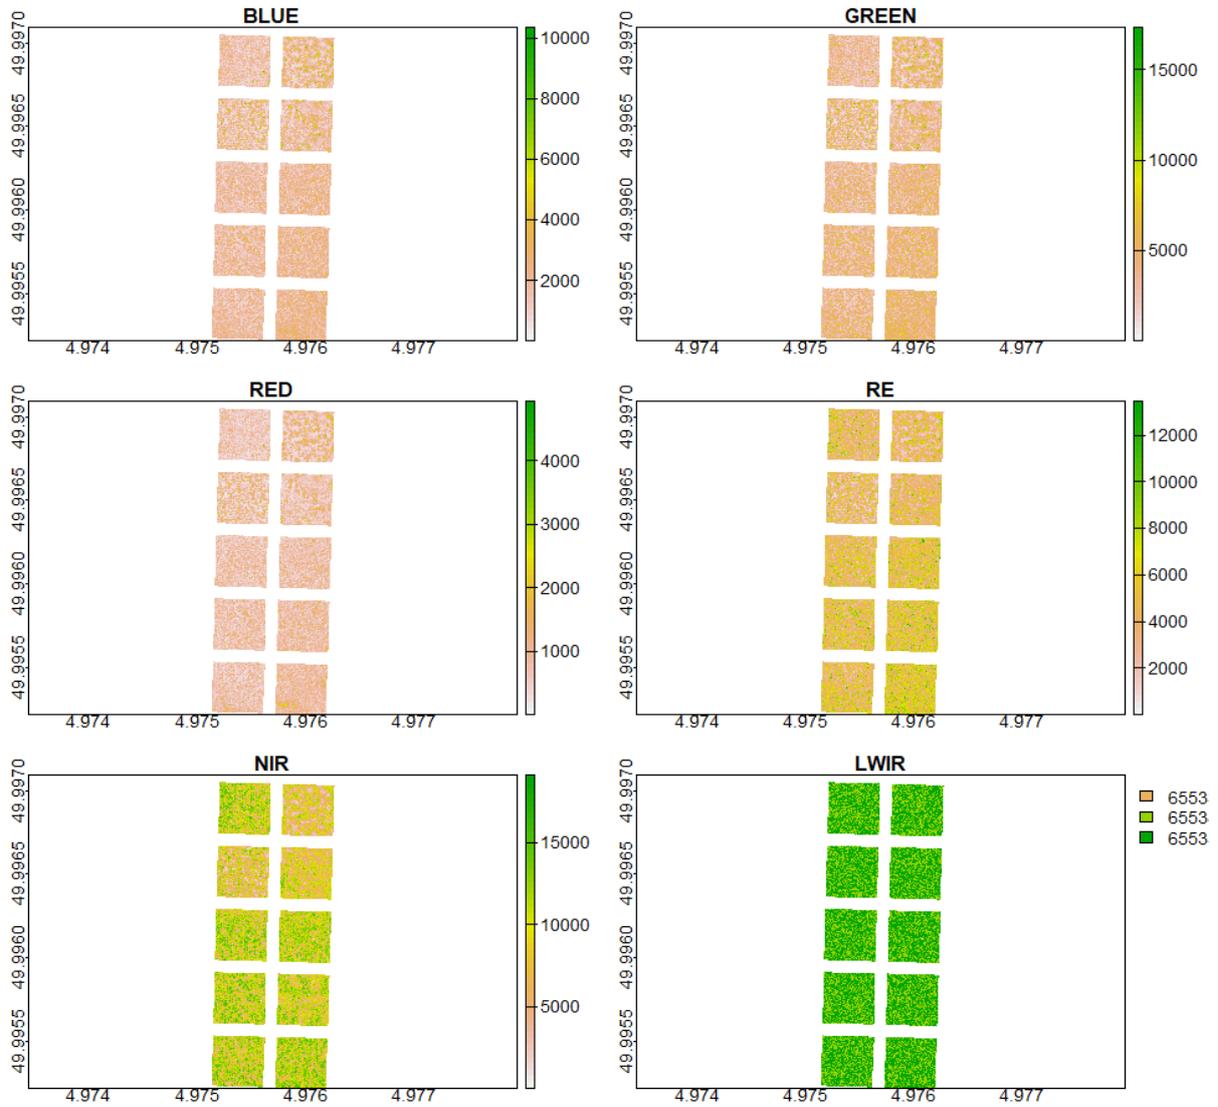

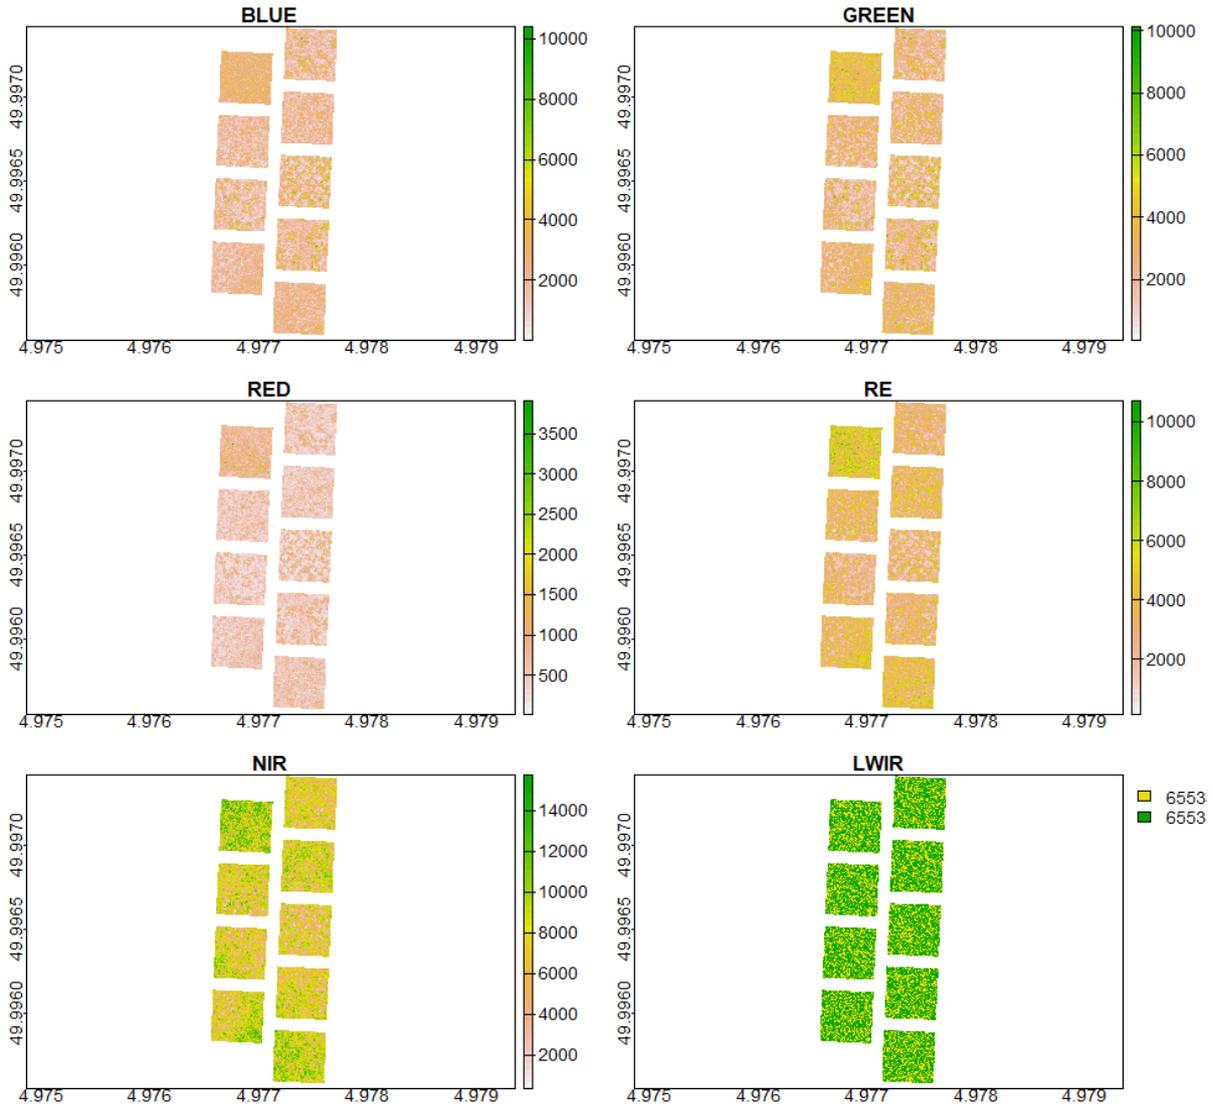

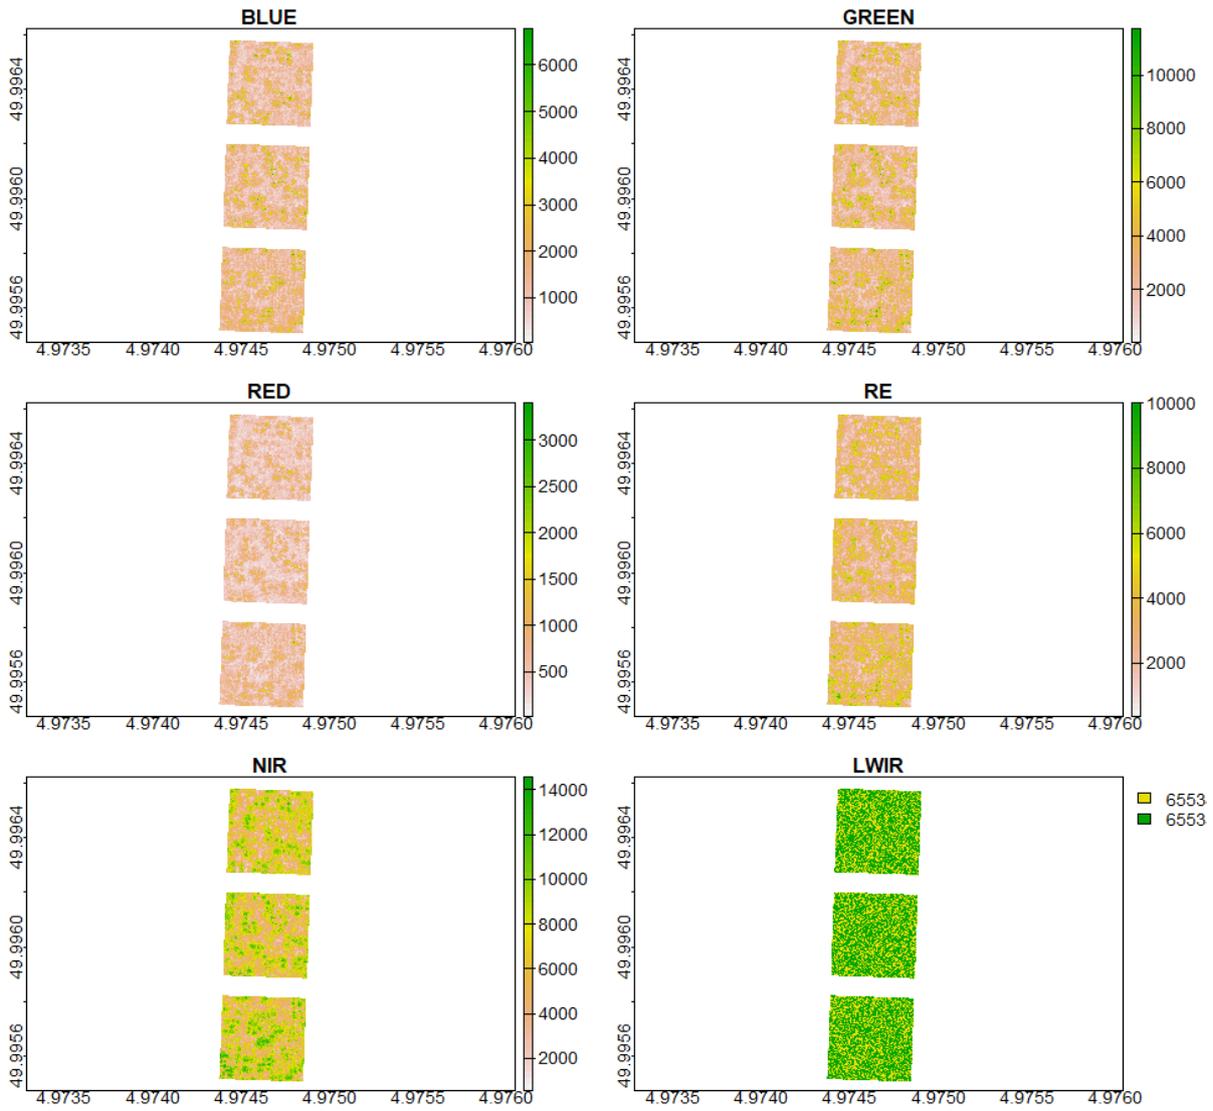

Appendix XIV Plant height in meters derived by subtracting the DTM of Flanders from the MAPEO-preprocessed DSM result. The results of the five different flight missions over the FORBIO site in Gedine (three in Gribelle and two in Gouverneurs) are given.

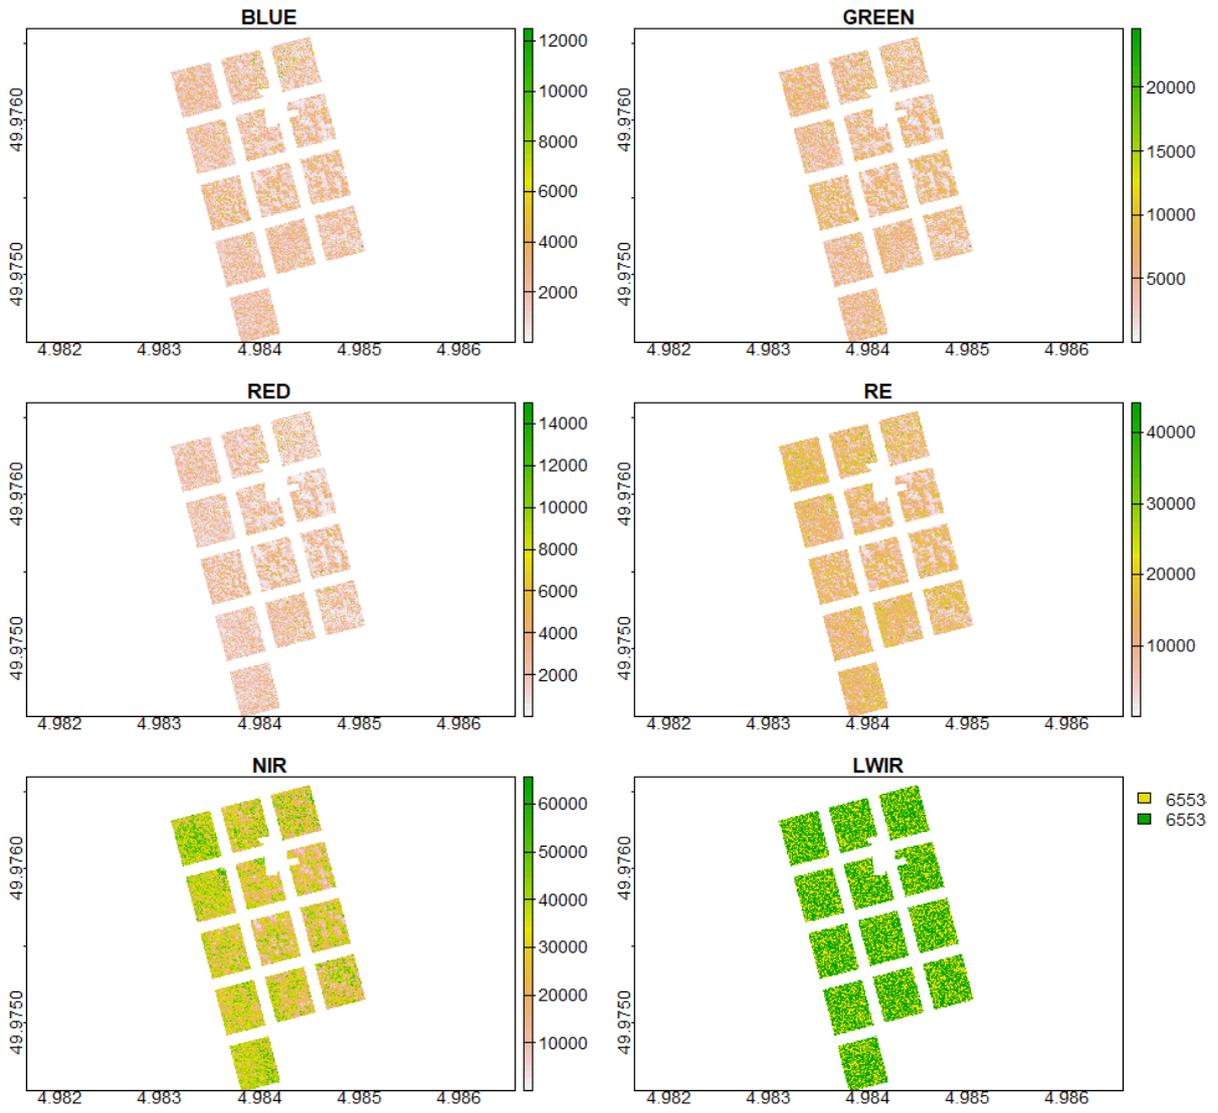

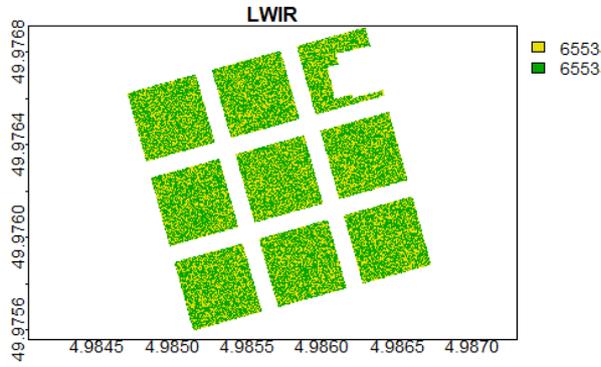

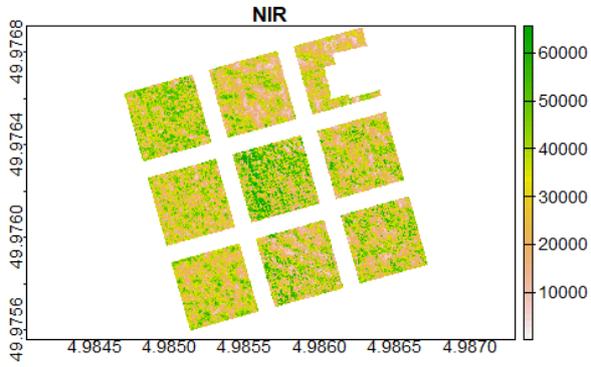

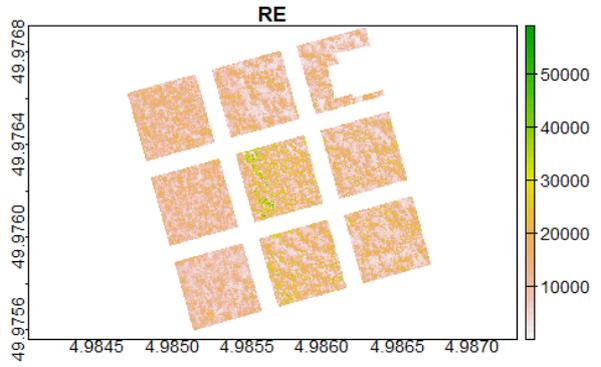

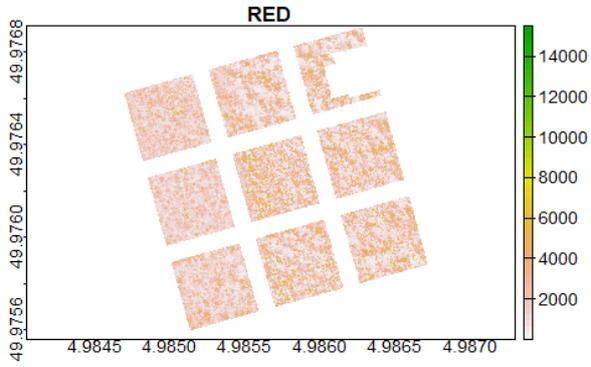

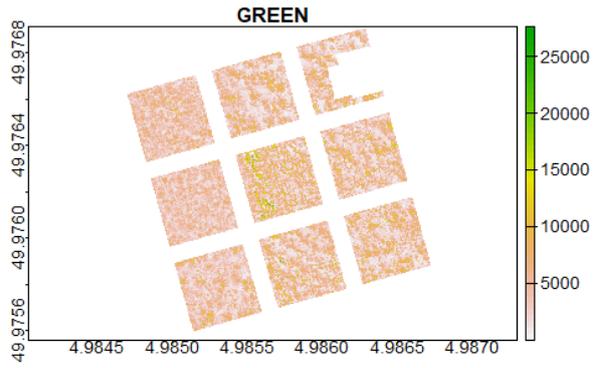

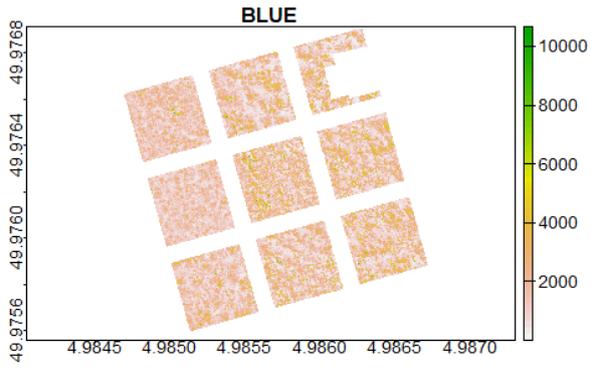

Appendix XV Reflectance drone data after clipping with size-reduced plots of the FORBIO site in Gedinne. Six different bands are presented from left to right: blue, green, red, red edge (RE), near-infrared (NIR), longwave infrared (LWIR). The results of the five different flight missions over the FORBIO site in Gedinne (three in Gribelle and two in Gouverneurs) are given (continued next pages).

Appendix XVI Absolute value of correlation between the different variables. The values higher than 0.7 are given in bold.

Appendix XVIII For the plots at the FORBIO site in Hechtel-Eksel, represented by plot ID, the mean and standard deviation (sd) of different reflectance bands are given: blue, green, red, red edge (RE), near infrared (NIR) and longwave infrared (LWIR). These values are a result after clipping with the reduced plot sizes, correcting for the alpha band and applying the mask layer to eliminate dead or unhealthy vegetation pixels.

| Plot ID | Blue | Green | Red | RE | NIR | LWIR | Blue sd | Green sd | Red sd | RE sd | NIR sd | LWIR sd |
|---------|------|-------|------|-------|-------|-------|---------|----------|--------|-------|--------|---------|

Appendix XIX For the plots at the FORBIO site in Hechtel-Eksel, represented by plot ID, the correlation of variance (cv) of different reflectance bands are given: blue, green, red, red edge (RE), near infrared (NIR) and longwave infrared (LWIR). The mean, standard deviation (sd) and cv of the NDVI and the corrected plant height (PH) are presented as well. These values are a result after clipping with the reduced plot sizes, correcting for the alpha band and applying the mask layer to eliminate dead or unhealthy vegetation pixels.

| Plot ID | Blue cv | Green cv | Red cv | RE cv | NIR cv | LWIR cv | NDVI | NDVI sd | NDVI cv | PH | PH sd | PH cv |

Appendix XXI For the plots at the FORBIO site in Zedelgem, represented by plot ID, the mean and standard deviation (sd) of different reflectance bands are given: blue, green, red, red edge (RE), near infrared (NIR) and longwave infrared (LWIR). These values are a result after clipping with the reduced plot sizes, correcting for the alpha band and applying the mask layer to eliminate dead or unhealthy vegetation pixels.

| Plot ID | Blue | Green | Red | RE | NIR | LWIR | Blue sd | Green sd | Red sd | RE sd | NIR sd | LWIR sd |

Appendix XXII For the plots at the FORBIO site in Zedelgem, represented by plot ID, the correlation of variance (cv) of different reflectance bands are given: blue, green, red, red edge (RE), near infrared (NIR) and longwave infrared (LWIR). The mean, standard deviation (sd) and cv of the NDVI and the corrected plant height (PH) are presented as well. These values are a result after clipping with the reduced plot sizes, correcting for the alpha band and applying the mask layer to eliminate dead or unhealthy vegetation pixels.

| Plot ID | Blue cv | Green cv | Red cv | RE cv | NIR cv | LWIR cv | NDVI | NDVI sd | NDVI cv | PH | PH sd | PH cv |

Appendix XXIV For the plots at the FORBIO site in Gedinne, represented by plot ID, the mean and standard deviation (sd) of different reflectance bands are given: blue, green, red, red edge (RE), near infrared (NIR) and longwave infrared (LWIR). These values are a result after clipping with the reduced plot sizes, correcting for the alpha band and applying the mask layer to eliminate dead or unhealthy vegetation pixels.

| Plot ID | Blue | Green | Red | RE | NIR | LWIR | Blue sd | Green sd | Red sd | RE sd | NIR sd | LWIR sd |
|---------|------|-------|------|-------|-------|-------|---------|----------|--------|-------|--------|---------|

Appendix XXV For the plots at the FORBIO site in Gedinne, represented by plot ID, the correlation of variance (cv) of different reflectance bands are given: blue, green, red, red edge (RE), near infrared (NIR) and longwave infrared (LWIR). The mean, standard deviation (sd) and cv of the NDVI and the corrected plant height (PH) are presented as well. These values are a result after clipping with the reduced plot sizes, correcting for the alpha band and applying the mask layer to eliminate dead or unhealthy vegetation pixels.

| Plot ID | Blue cv | Green cv | Red cv | RE cv | NIR cv | LWIR cv | NDVI | NDVI sd | NDVI cv | PH | PH sd | PH cv |

8 Popularised Summary

Today, biodiversity is declining faster than ever known in human history. This huge loss of species threatens all kind of benefits that nature provides us. Think off clean drinking water, carbon uptake, recreation... Without taking conservation actions, the rate of species extinction will accelerate even more, which is a direct threat to human existence. To be able to conserve species, one needs to have a clear picture of how many species live where and how well they are performing. However, doing this through traditional field surveys is very time-consuming and costly. A recently discovered solution for this is using drones. Drones can easily collect very detailed data and can even capture information that is not visible to the naked eye. Because this is a rather new field of research, much remains to be discovered.

In this research, we tried to predict species diversity and productivity at the FORBIO tree experiment sites in Belgium. At these sites, different tree species are planted in plots where some plots contain one species only (monocultures) and in other plots different species are mixed together. To collect data, drone flight missions were carried out over these sites. A multispectral sensor attached to the drone captured reflectance data in different parts of the electromagnetic spectrum e.g. visible part, infrared part... For all these bands, the mean, standard deviation and correlation of variance were calculated per plot and this information was used to build models to predict tree species richness on the one hand and tree productivity on the other hand. Different models were tested, but none were very good in predicting species richness. However, by adding information of the tree height the model accuracy increased significantly.

The models to predict tree productivity performed better. Generally, a higher productivity was found in mixed-species plots compared to monoculture plots. This confirms the theory that it is better to plant mixed forest. These research results indicate that data collected with drones can indeed be used in tree biodiversity and productivity studies in addition to traditional field surveys.
